Figure 34-41. Tumor recurrence at the incisional wound after surgery for gastric cancer. CT scan shows a lobulated, well-enhancing mass (M) along the incisional wound as well as a large amount of ascites and peritoneal thickening due to peritoneal carcinomatosis. (From Ha HK, Kim HH, Kim HS, et al: Local recurrence after surgery for gastric carcinoma: CT findings. *AJR Am J Roentgenol* 161:975-977, 1993.)

Figure 34-42. Gastric lymphoma. Gastric wall is markedly thickened (M) with predominant involvement of the submucosa. The mucosal layer is well preserved.

of invasion and regional lymph node involvement play a decisive role in survival.⁶⁰ Unlike carcinoma, lymphoma tends to spread laterally within the submucosal plane and spares the muscular coats until late in its course.

With its ability to directly image the entire gastric wall and adjacent structures, CT has proved capable of determining the extent of spread of gastric lymphoma with a high degree of accuracy.⁶⁹ According to Megibow and colleagues,³⁹⁸ gastric wall involvement can be divided into three patterns, as seen with CT:

1. Diffuse infiltration involving more than 50% of the length of the stomach.
2. Segmental infiltration.
3. The localized polypoid form.

Gastric wall thickening is most commonly circumferential, with thickness greater than 4 cm. Thickening and distortion of the gastric rugal folds may be present but outlet obstruction is rare (Fig. 34–42).^{69, 398} Dynamic CT and MRI clearly depict submucosal spread of the tumor within the normally enhanced mucosal layer (Fig. 34–43).⁴⁰⁸ Lymphomatous tissues in the thickened gastric wall usually show poor and homogeneous contrast enhance-

ment; this pattern may be due to lack of desmoplastic response in lymphoma in contrast with gastric adenocarcinoma.

Sometimes gastric lymphoma shows heterogeneous enhancement. In such cases, the hypoattenuated areas may be caused by the pathologic evidence of necrosis and hemorrhage.²³² The localized polypoid form is often associated with an ulcer. The perigastric fat plane is usually preserved. Most patients with gastric lymphoma have perigastric lymphadenopathy, and the presence of widespread retroperitoneal lymphadenopathy indicates systemic disease.

Perforation is an important complication affecting therapy and prognosis. It may occur in 9% to 47% of patients as a result of the lack of desmoplastic response, the rapid growth of the tumor, or a response to therapy.³⁹³ Tumor extension into the esophagus is present in about 10% of patients, and spread across the pylorus into the duodenal bulb has been noted in approximately one third of patients.²⁴⁵ Although not common, far-advanced cases of lymphoma can show diffuse peritoneal involvement with ascites, omental infiltration, and peritoneal implants, mimicking carcinomatosis (Fig. 34–44).²⁹⁸

Figure 34–43. Gastric lymphoma. A, A mass (M) is seen in the gastric wall along the lesser curvature of the stomach on CT scan. B, T2-weighted MR image shows a mass (M) with intermediate signal intensity. C and D, Dynamic gadolinium-enhanced MR images show poor contrast enhancement of the mass (M) in the early phase (C) and isointensity to that of the liver in the delayed phase (D).

Figure 34-44. Peritoneal lymphomatosis. CT scan shows omental cake (arrows) and diffuse mesenteric infiltration.

Gastrointestinal Stromal Tumor

GI stromal tumors are the most common primary nonepithelial neoplasms of the stomach and small bowel. For many years, they were all regarded as being basically of smooth muscle nature; they were designated as leiomyomas and leiomyosarcomas when composed of spindle cells and as benign or malignant leiomyoblastomas when composed of epithelioid cells.

GI stromal tumors can be divided into four major categories on the basis of their phenotypical features⁵¹⁰:

1. Tumors with features of smooth muscle differentiation.
2. Tumors with features of neural differentiation.
3. Tumors with dual differentiation in smooth muscle and neural elements.
4. Tumors lacking differentiation in either cell type.

Tumors with features of neural differentiation are currently regarded as malignant, and tumors with dual differentiation and with none of smooth muscle and neural differentiation are regarded as malignant or potentially malignant. Tumors with features of smooth muscle differentiation may be benign, borderline, or malignant. Features favoring malignancy are size larger than 5 cm, necrosis,

Figure 34-46. Malignant gastrointestinal stromal tumor. CT scan shows a large, heterogeneous mass (m) growing exophytically from the stomach (arrow).

hemorrhage, hypercellularity, nuclear atypia, and mitotic activity.

The location of the tumor in the gastric wall is submucosal in about 60%, subserosal in about 30% and intramural in 10%. Ninety percent of gastric stromal tumors are in the fundus and body. Growth is usually in an exogastric fashion or dumbbell shaped.³⁹⁷

Dynamic CT may demonstrate the location of stromal tumor in the submucosal layer and the intact mucosal layer (Fig. 34-45). Most stromal tumors are enhanced heterogeneously on CT,⁹³ with common occurrence of low attenuated areas owing to internal hemorrhage, necrosis, or cystic changes (Fig. 34-46)⁴⁸¹; the presence of hemorrhage produces fluid-fluid level within the mass. Areas of necrosis can give the appearance of multiple, thick septations within the tumor. Necrosis within the tumor mass may lead to excavation and communication with the GI tract or perforation into the peritoneal cavity.

In one series,⁵⁰⁵ crescent-shaped necrosis caused by necrosis in the periphery of the extraluminal component of the mass was reported to be suggestive of a stromal tumor on CT. Ulceration of the overlying mucosa can be demonstrated on CT as the presence of air or an oral contrast agent. Another cause of gas within the mass may be superinfection of the necrotic tumor (Fig. 34-47).⁵²²

Figure 34-45. Benign gastrointestinal stromal tumor (M) of the stomach with poor contrast enhancement in the early phase (A) of the dynamic CT study and marked enhancement in the delayed phase (B).

Figure 34-47. Infected malignant gastrointestinal stromal tumor of the stomach. CT scan shows a large, heterogeneous mass (arrows) with central cavitation and gas collection. The small orifice of the ulcer in the tumor was considered to be the cause of secondary infection.

Although not common, calcification is seen in stromal tumors (Fig. 34-48). Compared with adenocarcinoma, stromal tumors tend to show much less local invasiveness. Lymphatic spread and intraperitoneal fluid collection are also less common but do occur. The most common sites of metastases of stromal tumors are the liver, peritoneum, and lungs. Intraperitoneal tumor seeding (leiomyosarcomatosis) occurs directly along mesenteric reflections via ascitic fluid or embolic metastases.⁴⁰⁵ The incidence is high in patients with tumors that are exposed to the peritoneal cavity along with local invasiveness. On follow-up CT scans, both paracolic gutters and pelvic cavity should be carefully evaluated for the presence of small nodule or granular infiltration. The CT appearance of leiomyosarcomatosis does not differ significantly from that of peritoneal carcinomatosis of other origin, but the incidence of peritoneal nodules was much higher in stromal tumors (see Fig. 34-82).⁵⁹⁰

Hasegawa and colleagues²²⁶ reported the usefulness of

Figure 34-48. Benign gastrointestinal stromal tumor of the stomach. A calcified mass (arrow) is seen in the high body and fundus of the stomach.

MRI in nine patients with gastric stromal sarcomas. MRI was helpful not only in determining the relationships between the mass and gastric wall or surrounding organs but also in detecting intratumoral hemorrhage and necrosis. High-grade stromal tumors showed ill-defined borders, whereas low-grade tumors showed well-defined margins.

Metastatic Tumor

Hematogenous metastases may be discovered during abdominal CT performed for other reasons. Malignant melanoma and breast and lung carcinoma are the usual primary lesions. Metastasis from a lobular carcinoma of the breast produces a linitis plastica pattern of gastric wall thickening (Fig. 34-49).⁸¹ Squamous carcinoma of the esophagus reportedly involves the gastric cardia in up to 15% of patients and may simulate a primary mucosal or submucosal neoplasm.¹⁸² Carcinomas of the transverse colon and tail of the pancreas metastasize to the gastric wall by direct extension via the gastrocolic and splenorenal-gastrosplenic ligaments, respectively.

Liposarcoma

Gastric liposarcoma originates in undifferentiated mesenchymal cells present within the submucosa and tunica muscularis of the gastric wall.³¹³ Pathologically, four forms are recognized: (1) differentiated, (2) myxoid, (3) round cell, and (4) pleomorphic.

The exuberant exophytic growth explains the lack of specific GI symptoms and the delayed diagnosis. The CT appearances correlate with the macroscopic appearance of the neoplasm. Fatty areas within the tumor is reported only in the differentiated form.³⁵⁴ Undifferentiated liposarcomas commonly contain areas of necrosis and hemorrhage along with prominent enhancement of the solid zones.¹⁵² Myxoid tumors present as a cystic form owing to the presence of gelatinous matrix.¹⁵²

Plasmacytoma

Malignant neoplasms of plasma cells (plasmacytoma) appear in two forms. The *diffuse* form includes multiple myeloma or plasma cell leukemia; the *local* form is a solitary myeloma of bone or an extramedullary plasmacytoma. Ten percent of cases of extramedullary plasmacytoma occur in the GI tract; the small bowel is most commonly involved, followed by the stomach, colon, and esophagus. Primary gastric plasmacytoma accounts for approximately 5% of all extramedullary plasmacytomas.²³⁰

The diagnosis of primary gastric plasmacytoma is established by the absence of a serum M protein component; hence, there is no Bence-Jones proteinuria, no bone marrow infiltration, and no visceral involvement other than of the stomach.⁵¹⁷

Pathologically, primary gastric plasmacytoma has been thought to originate from lymphoid follicles in the submucosa or from plasma cells in the lamina propria of the mucosa and can have various forms. Remingo and Klaum⁴⁹⁷ grossly classified gastric plasmacytoma into four types: (1) *nodular*, (2) *infiltrative*, (3) *ulcerative*, and (4) *polypoid*. Of these four types, the nodular type was most commonly seen in their study. CT findings of gastric plasmacytoma simulate those of lymphoma or a mucinous type

Figure 34-49. Metastasis to the stomach (linitis plastica) from breast cancer. *A*, Double-contrast upper gastrointestinal series shows focal luminal narrowing (arrows), rigidity, and fold thickening in the proximal antrum and lower body of the stomach. *B*, CT scan shows involvement of the stomach by a scirrhous tumor.

of gastric cancer owing to poor contrast enhancement of the gastric wall (Fig. 34-50).⁶¹⁴ Deep endoscopic biopsy, combined with the immunohistochemical study of immunoglobulin, is essential in diagnosis.⁵³²

Benign Gastric Tumors

Gastric Polyp and Adenoma

Epithelial polyps of the stomach may be *hyperplastic* or *adenomatous*.

Hyperplastic polyps are not true neoplasms. They are believed to develop from excessive regeneration of superficial epithelium. Although most of these non-neoplastic

polyps are often multiple and smaller than 1.5 cm in diameter, 9% are larger than 2 cm.⁴⁰⁹

In contrast, 80% of adenomatous polyps (adenoma) exceed that size.⁴⁰⁹ CT may detect epithelial polyps that are larger than 2 cm in diameter when the stomach is well distended with air or when oral contrast material has been given (Fig. 34-51). No specific CT features that can distinguish these polyps from gastric malignancy have been reported. Rarely, pedunculated polyps may prolapse into the duodenum or may cause intussusception (Fig. 34-52).²¹⁶

Lipoma

Gastric lipoma is a rare submucosal tumor that usually occurs in the antrum. Large lipomas ulcerate and produce

Figure 34-50. Gastric plasmacytoma. *A*, Upper gastrointestinal radiograph shows large gastric mass (arrows) with a sharply margined border. *B*, CT scan shows marked gastric wall thickening (arrows) with poor contrast enhancement simulating lymphoma or adenocarcinoma. (From Yoon SE, Ha HK, Lee YS, et al: Upper gastrointestinal series and CT findings of primary gastric plasmacytoma: Report of two cases. *AJR Am J Roentgenol* 173:1266-1268, 1999.)

Figure 34-51. Gastric adenoma with malignant transformation. CT scan shows a polypoid mass (M) with a short, thick stalk.

clinically significant hemorrhage.³⁶⁵ The CT finding of gastric mass having a CT attenuation equivalent to fat is pathognomonic of a gastric lipoma (Fig. 34-53).

Hemangioma

Gastric hemangiomas are rare neoplasms, constituting less than 2% of all benign tumors of the stomach. Pathologically, hemangiomas can be (1) cavernous, (2) capillary, or (3) mixed. The gross appearance varies according to the size and density of the plexus of vessels forming the lesion, the degree of arteriovenous shunting, and the presence of thrombosis or fibrosis.

Cavernous hemangiomas may be single or multiple, localized, or diffuse.^{180, 285} Gastric hemangiomas are smooth submucosal masses that are radiographically indistinguishable from stromal tumors. Although rare, the presence of phleboliths, which are most often associated with the cavernous types, help in establishing an accurate diagnosis on CT.⁵³⁷

Gastroduodenal intussusception due to prolapsed gastric adenoma. *A*, Radiograph shows a large polypoid mass (arrowheads) in the antrum of the stomach. *B* and *C*, CT scans obtained 1 month later after an upper gastrointestinal series show large soft tissue mass (arrows) in the duodenum and beaklike narrowing (small arrows) of the distal stomach. (From Ha HK, Shinn KS, Kim IC, et al: Gastroduodenal intussusception due to a prolapsed gastric adenoma. *AJR Am J Roentgenol* 159:432, 1992.)

Figure 34-53. Gastric lipoma. A fatty mass (M) is seen in the antrum.

Inflammation and Other Conditions

Peptic Ulcer Disease

Although CT has no useful role in patients with uncomplicated peptic ulcer disease, it is effective in detecting its complications such as acute free perforation and penetration. The ulcers are frequently identified on CT as round, thin-walled collections of air or orally administered contrast medium, projecting beyond the confines of the gastric or duodenal lumen. Although direct visualization of the ulcer may be difficult on CT in many instances, the involved gastric or duodenal wall is mostly thickened with considerable mural edema (Figs. 34-54 and 34-55). If free perforation is present, CT may show free extravasation of oral contrast material or free intraperitoneal air, or both,

Figure 34-55. Benign gastric ulcer. The swollen gastric wall surrounding the gastric ulcer simulates a polypoid mass (P). Gastric wall thickening (arrows) is also present.

along with evidence of diffuse peritonitis such as omental or mesenteric infiltration and intraperitoneal fluid collection.

Although CT is not very accurate in detecting the perforating site,^{262, 366} the use of thin-section spiral CT may improve detection by demonstrating the interruption of well-enhanced gastric wall.⁴³⁷ On occasion, peptic ulcers that extend beyond the serosa of the bowel wall may penetrate the adjacent structures (confined perforation or penetration). The most common site of penetration is the pancreas owing to an ulcer's proximity to the distal stomach and duodenum and fixation of its position³⁶⁶; other sites include the gastrohepatic omentum, the biliary tree, and the liver, with the omentum being involved by gastric ulcers and the biliary tree by duodenal ulcers.²²⁷ On CT, the diagnosis of ulcer penetration can be confirmed when a low-density linear band (sinus tract) containing perigastric contrast material is identified or when an ectopic pocket of

Figure 34-54. Benign gastric ulcer. **A**, A large, penetrating ulcer (U) is seen in the posterior wall of the stomach with markedly enhancing inner layer of the thickened gastric wall and edematous outer layer (arrows). Minimal perigastric infiltrate is also seen. A lipoma (L) is incidentally found in the duodenum. **B**, Double-contrast upper gastrointestinal series shows a large ulcer crater (U) with convergence of thickened gastric wall.

Figure 34-56. Confined peptic ulcer perforation. CT scan shows a perigastric cystic mass (A) with a thick peripheral wall in the perigastric region. The wall of the stomach and duodenum is considerably thickened with heterogeneous contrast enhancement (arrows) and evidence of perigastric infiltrates is present.

gas is demonstrated in the perigastric space adjacent to the suspected ulcer crater (Figs. 34-56 and 34-57).

In cases of pancreatic penetration, the fat plane between the ulcer and the pancreas is lost and the pancreas is focally enlarged with diminished CT attenuation, findings that are indistinguishable from those of acute pancreatitis. However, despite pancreatic enlargement, the remaining peripancreatic fat plane is commonly preserved, and only a small number of patients may show an increased level of serum amylase or lipase in such instances.²⁶² CT can also depict penetration of a gastric ulcer crater or its surrounding inflammatory mass into the splenic parenchyma.¹⁸¹

Gastritis and Other Conditions Causing Gastric Wall Thickening

Gastritis, recently associated with *Helicobacter pylori* infection, commonly involves the antrum and body of the

Figure 34-57. Confined duodenal ulcer perforation. CT scan shows edematous bowel wall thickening of the duodenum with an ulcer crater (arrow). A small amount of fluid is collected in the paraduodenal space.

stomach, with most cases involving the antrum.⁵⁸⁴ Enlargement of gastric folds and thickening of the gastric wall may occur owing to a combination of mucosal inflammation, submucosal edema, and secondary hypertrophy and hyperplasia of the gastric mucosa. Gastritis appears as circumferential or focal gastric wall thickening on CT.⁵⁸⁴

Although CT is sensitive in detecting inflammatory processes in the stomach, it is not specific in differentiating gastritis from gastric malignancy. The absence of obliteration of the fat planes, perigastric infiltration, and lymphadenopathy may aid in diagnosis. Other infectious processes, such as toxoplasmosis and cryptosporidiosis, can also cause nonspecific gastric wall thickening.^{548, 551}

In rare instances of acute infectious gastritis, an intramural gastric wall abscess develops, simulating a submucosal tumor.¹⁰⁴ In patients with emphysematous gastritis, CT may show an irregular, thickened gastric wall along with multiple intramural gas bubbles. When intramural gas is seen with noninfectious causes of gastric emphysema, such as secondary to gastric outlet obstruction, the gas is distributed as thin, uniform linear streaks.³⁷⁷ Although rare, chronic granulomatous disease can involve the stomach, especially along the antrum, with diffuse nonspecific gastric wall thickening on CT.

Menetrier's disease shows diffuse thickening of the gastric mucosal folds, predominantly along the body and fundus of the stomach (Fig. 34-58).¹⁵⁷ In immunocompromised patients, graft-versus-host disease (GVHD) may demonstrate not only gastric wall thickening on CT but also a peculiar, persistent coating of the gastric and small-bowel mucosa with orally administered contrast material.²⁷² CT also demonstrates gastric fold or wall thickening in Zollinger-Ellison syndrome (Fig. 34-59), amyloidosis, sarcoidosis, and eosinophilic gastritis. An extragastric inflammatory process, such as acute pancreatitis, may involve the gastric wall with focal thickening or cystic mass formation (Fig. 34-60).

Congenital Conditions Diverticula

Gastric diverticula generally arise from the posterior wall of the fundus. They appear as a thin-walled, cystic-

Figure 34-58. Ménétrier's disease of the stomach. CT scan shows marked thickening (arrows) of the gastric rugal folds along the greater curvature of the stomach.

Figure 34-59. Gastric fold thickening due to gastrinoma. CT scan shows marked gastric distention and fluid excess with prominent and thickened mucosal folds (*arrowheads*). A small mass (*arrow*), which was confirmed as gastrinoma at surgery, is noted in the perigastric region.

appearing mass on CT (Fig. 34-61). If the diverticulum is not filled with air or orally administered contrast material, it simulates a cystic inflammatory or neoplastic condition of adjacent structures.

Ectopic Pancreatic Rest

The ectopic pancreas pathologically appears as a smooth nodule and, occasionally, as a mass with an irregular surface. It is usually situated in the submucosa and only occasionally expands into the muscularis. It most frequently occurs in the antrum within 3 to 6 cm of the pylorus and is on the greater curvature side of the posterior wall of the stomach; other sites include the second portion of the duodenum and the jejunum.³² On barium study, demonstration of umbilication, which represents the filling of the rudimentary pancreatic duct, may suggest the proper diagnosis.⁵⁷¹ When a nodule exceeds 2 cm, it appears as a mural nodule on CT (Fig. 34-62).

Figure 34-60. Gastric wall involvement in a patient with pancreatitis. CT scan shows a cystic mass (P) in the gastric wall due to extension of pancreatic pseudocyst.

Figure 34-61. Gastric diverticulum. CT scan shows a diverticulum (D) arising from the posterior wall of gastric fundus, which is filled with oral contrast material and gas.

Gastric Duplication

Most gastric duplications occur during the first year of life, but 28% of cases have been detected in patients older than 12 years of age.⁴⁷² Approximately 82% are spherical cysts and do not communicate with the stomach; the remaining 18% are tubular and communicate with the gastric lumen.⁶⁰¹ Although rare, pedunculated type of duplication with a thin, fibrous strand is also reported.³⁰⁹ The most common location is along the greater curvature, followed by posterior wall, lesser curvature, anterior wall, and pylorus.

Ectopic pancreatic tissue is found in the wall of up to 37% of gastric duplications²³⁹ and is associated with pancreatitis and elevated amylase levels. Detection of associated vertebral anomalies such as spina bifida, hemivertebra, and complete vertebral body cleft is a helpful clue for the diagnosis.

Clinically, duplications occur twice as often in girls than

Figure 34-62. Ectopic pancreas in the stomach. CT scan shows a submucosal mass (M) in the prepyloric antrum of the stomach.

in boys. Clinical symptoms and signs include a palpable mass, gastric obstruction, abdominal pain, melena, or hematemesis. Gastric duplication may undergo torsion and may perforate and cause a surgical emergency.⁵³¹

CT and MRI may be used to determine the nature, size, and extent of the mass, revealing a cystic mass contiguous with the stomach and containing fluid, gas, or debris. Curvilinear calcification is rarely detected on the wall of the duplication.¹⁶²

The differential diagnosis with other disease entities such as pancreatic cyst and pseudocyst, mesenteric cyst, and various intramural tumors of the stomach cannot be easily made by imaging findings alone. Technetium 99m-pertechnetate may show uptake of the radiopharmaceutical agent in the gastric mucosal lining.

Other Conditions

Varices

Esophageal and gastric varices develop in patients with portal hypertension either as a consequence of intrahepatic obstruction (cirrhosis) or extrahepatic obstruction, such as portal or splenic vein occlusion. In contrast to the superficial location beneath the mucosa in esophageal varices, gastric varices tend to have a subserosal location and are thereby easily mistaken at endoscopy or radiographic studies for other submucosal masses.^{79, 376}

In the stomach, the posteromedial border of the gastric fundus is the most common site, although any part of the stomach can be involved. CT is a sensitive tool for detecting gastric varices and for determining their primary cause. Gastric varices appear as well-defined clusters of markedly enhancing, rounded, and tubular lesions within the scalloped gastric wall (Fig. 34–63).⁷⁹ Intra-abdominal collateral venous channels may also be seen along the distribution of the left gastric, gastroepiploic, or short gastric vein.

Figure 34–63. Esophageal varices after sclerotherapy in a patient with liver cirrhosis. CT scan shows esophageal wall thickening with target appearance. The middle layer (arrows) appears hypo-attenuated, presumably owing to mural hematoma or edema.

Gastroduodenal Intussusception

Gastroduodenal intussusception is an uncommon condition reported to be caused by benign pedunculated gastric tumors such as stromal tumor, adenoma, and lipoma or Menetrier's disease.^{122, 216} CT findings are characteristic. The site of the invagination is seen as a target-like mass in the duodenal region. Both CT and barium study may also show foreshortening and beaklike narrowing of the distal stomach as well as gastric outlet obstruction (see Fig. 34–52).^{122, 216}

Jejunogastric Intussusception

Jejunogastric intussusception is a rare complication of gastric surgery that may present either in acute form or as a chronic recurrent process. According to the type of invaginated loop, it can be classified as an *afferent* loop invagination or as an *efferent* loop invagination or both.⁵³⁴ The efferent loop invagination is most commonly seen.

Retrograde peristalsis is considered to be the main pathogenetic factor. Immediate laparotomy should be performed because an 80% mortality rate has been reported when treatment is delayed.⁹⁶

Although the diagnosis can be made with an upper GI series or gastroscopy, CT is also useful in diagnosis and in early detection of possible strangulation in the intussuscepted jejunal loop. CT may show dilatation of the gastric remnant with evidence of intragastric position of the jejunal loop and mesentery (Fig. 34–64).^{348, 353}

Gastric Herniation and Volvulus

The diagnosis of gastric herniation through the lacerated diaphragm is often delayed or missed because its plain radiographic appearance resembles that of pneumothorax, hemothorax, pleural effusion, pulmonary consolidation or collapse, or raised hemidiaphragm. In addition to the penetrating or blunt trauma to the diaphragm, laxity or absence of the tethering gastric ligaments as well as conditions that increase the size of the esophageal hiatus, such as rapid changes in intra-abdominal pressure (i.e., trauma), and de-

Figure 34–64. Transient jejunojejunal intussusception after gastrectomy. CT scan shows heterogeneous masslike lesion in the jejunal loop caused by invagination of the regional mesentery into the bowel lumen. Small-bowel follow-through study (not shown) did not demonstrate any mass.

Figure 34-65. Delayed post-traumatic diaphragmatic hernia. *A*, CT scan shows herniation of the proximal part of the stomach (H) into the thorax as well as evidence of disruption of the left crus of the diaphragm (arrows). *B*, Barium study shows gastric obstruction with markedly distended, herniated intrathoracic stomach (S).

generative changes (i.e., aging) may also predispose to herniation and volvulus of the stomach.

Herniation may involve the fundus only or much of the body and antrum. In this condition, a nasogastric tube may show a normal position at the esophagogastric junction but then pass up into the chest, although such findings can be seen in the presence of an elevated left diaphragm. A barium study may show the intrathoracic position of the herniated stomach as well as a waistlike constriction in the stomach where the stomach passes through the diaphragm.

Although CT may be suboptimal in evaluating the diaphragm, several reports acknowledge its success (Fig. 34-65).^{228, 582} The use of additional reformatted images in

coronal or sagittal plane helps to facilitate detection of diaphragmatic abnormalities. MRI, especially with coronal or sagittal T1-weighted images, is useful not only for establishing the diagnosis but also for localizing the site of lacerated diaphragm (Fig. 34-66). To determine the presence or absence of strangulation of the herniated stomach that is mainly caused by volvulus, IV infusion of the contrast material in both CT and MRI is mandatory.

Corrosive Gastric Injury

Corrosive agents produce extensive damage to the GI tract, with perforation or death occurring in the acute phase.

Figure 34-66. Delayed post-traumatic diaphragmatic hernia. Coronal T1-weighted (*A*) and half-Fourier acquisition single-shot turbo spin-echo (HASTE) (*B*) MR image clearly depicts gastric wasting (arrow) and the intrathoracic position of the herniated stomach (S). Note the hyperintense, thin diaphragm.

Figure 34-67. Corrosive gastritis after acid ingestion, with nearly complete loss of posterior wall of the stomach (S), as seen on this CT scan.

Alkaline caustic agents produce injury by liquefaction necrosis.¹⁸⁴ Fat and proteins become saponified, and blood vessels are thrombosed, leading to further cellular necrosis and degeneration. This characteristic of an alkali enhances its penetration into tissues, resulting in complete dissolution of the upper GI tract and damage of adjacent structures, including, in rare instances, even the transverse colon. In contrast to alkaline agents, concentrated acids produce a coagulative necrosis with a protective eschar that develops rapidly and may limit penetration to deeper muscle layer.²⁰²

The esophagus and stomach are the most common sites of involvement, but in severe cases significant liquefaction necrosis can occur both extraluminally and much more distally in the GI tract with the development of ischemia.⁴³³ Diagnostic evaluation of patients with corrosive injury should include examination of the entire esophagus, stom-

Figure 34-68. Corrosive gastritis with pneumatosis in the gastric wall and multifocal hepatic infarction. CT scan shows intramural gas (arrowheads) along with pneumoperitoneum (white arrow) and ascites due to gastric perforation. Also noted are intrahepatic portal vein gas (thin arrows) caused by hepatic infarction. (From Rha SE, Ha HK, Lee SH, et al: CT and MR imaging findings of bowel ischemia according to the various primary causes. *Radiographics* 20:29-42, 2000.)

ach, and duodenum by endoscopic or noninvasive methods. However, CT is useful in the evaluation of structures beyond the first site of the injury, thus avoiding the risk of instrumental perforation associated with endoscopy (Figs. 34-67 and 34-68).

Duodenum

Malignant Neoplasms

Primary Adenocarcinoma

Most cases of primary duodenal carcinomas usually occur in the periampullary region and in the third portions of the duodenum; the duodenal bulb involvement is extremely rare.¹⁰⁰ Duodenal adenocarcinoma may be associated with Gardner's syndrome, neurofibromatosis, celiac sprue, Crohn's disease, and Peutz-Jeghers syndrome.⁵¹⁰ Lesions situated more distally usually have a napkin-ring appearance and produce partial intestinal obstruction; about 20% have a predominantly polypoid or fungating appearance, probably caused by their origins in preexisting adenomatous polyps or villous adenomas.⁵⁸ Metastases are often present in the regional lymph nodes at the time of diagnosis, and thus the prognosis is poor.

On CT, primary duodenal adenocarcinomas appear as an intrinsic mass with a short segment of bowel wall thickening (Figs. 34-69 and 34-70).^{145, 281} The incidence of duodenal obstruction is common. When tumors invade the pancreas and biliary ducts, it may be difficult to distinguish these tumors from pancreatic and biliary tumors. With primary adenocarcinomas, the duodenal wall is more circumferentially thickened with a lesser degree of biliary and pancreatic duct dilation.

Lymphoma

Duodenal lymphoma is rare because the distribution of lymphoma is proportionate to the amount of lymphoid tissue. Characteristic CT features include a long segment of a large annular wall thickening along with aneurysmal dilatation of the lumen and bulky regional or more widespread lymphadenopathy (Fig. 34-71). In contrast to cases of primary adenocarcinoma, bowel obstruction is uncommon.

Figure 34-69. Primary duodenal adenocarcinoma.

Figure 34-70. Primary duodenal carcinoma. CT scan shows concentric bowel wall thickening (*arrow*), producing low-grade bowel obstruction. Note lymphadenopathy in the paraortic and periduodenal regions.

mon. In rare instances, the lymphoma involving the ampulla may produce biliary tract obstruction.⁵⁰

Metastatic Neoplasms

Direct invasion from tumors of the adjacent organs is the most important route for metastatic neoplasm of the duodenum. The primary tumor sites include the pancreas, stomach, gallbladder, liver, bile tract, right colon, and right kidney. In metastatic pancreatic or bile duct tumor, the medical aspect of the C-loop is involved with eccentric duodenal wall thickening. On the basis of CT findings alone, however, it may be difficult to ascertain whether the engulfing mass is of duodenal, bile duct, or pancreatic origin (Fig. 34-72).

Metastases from left colon carcinoma occur via the lymphatic drainage to the central mesenteric nodes surrounding the fourth portion of the duodenum or across the short fascial plane of the lateral reflection of the transverse mesocolon¹⁴⁵; it may cause duodenal or jejunal obstruction. Hematogenous and lymphatic metastasis to the duodenum

Figure 34-71. Duodenal lymphoma. CT scan shows irregular concentric bowel wall thickening (*arrows*) in the duodenum. Note lymphadenopathy along the root of mesentery and lymphomatous nodules in the liver.

Figure 34-72. Duodenal obstruction caused by direct tumor invasion of pancreatic cancer into third portion of the duodenum. CT scan shows irregular soft tissue mass (*arrows*) obstructing the duodenum (D) with marked distention of the stomach (S). Pancreatic cancer is not shown.

also occurs in lung and breast cancer (Fig. 34-73). In patients receiving chemotherapy for lung cancer, bowel obstruction and perforation may develop as a result of tumor necrosis in a metastatic lesion.³⁹² Gastric cancer may spread intramurally to the duodenum through submucosal lymphatic channels.¹⁴⁹

Non-neoplastic Conditions

Trauma

Because a large portion of the duodenum is within the retroperitoneum, most perforations occurring in these segments are clinically insidious. The horizontal segment

Figure 34-73. Metastasis to the duodenum from squamous cell carcinoma of the lung. CT scan shows a polypoid mass (m) protruding into the duodenal lumen.

of the duodenum crosses the vertebral column and is easily compressed against the spine by a direct blow. The distinction of duodenal perforation from an intramural hematoma without perforation is important because the latter condition does not require surgery.³⁴⁴

CT is becoming the most widely used modality for patients with abdominal trauma. The identification of extraluminal gas or extravasated oral contrast material or both in the right anterior pararenal space indicates the presence of duodenal perforation.³¹¹ Intramural duodenal hematomas are manifested on CT as tubular or ovoid, circumferential, or eccentric and heterogeneous wall thickening (Fig. 34-74); a curvilinear area of high density (*ring sign*) can be demonstrated inside the margin of the hematoma.⁶¹⁵ When the hematoma is resolved, the hematomas become cystic. Because of contiguity with the duodenum, it is important to search for an associated injury of the head of the pancreas.

Pancreatitis

The inflammation in pancreatitis may spread from the pancreas at the site of direct contact with the nonperitonealized posterior surface of the second part of the duodenum.³⁸ Once the barrier is crossed, the inflammatory process may extend along the wall of duodenum. The duodenal involvement in pancreatitis can be identified on CT by nonspecific wall thickening (Fig. 34-75). In rare instances, intramural duodenal pseudocyst develops³⁸⁸; CT attenuation in this pseudocyst is related to the presence or absence of hemorrhage, cells, or proteinaceous material. In such cases, CT differentiation of duodenal pseudocyst from duodenal duplication cyst, choledochocoele, or cystic dystrophy of the duodenal wall is often difficult.

Cystic Dystrophy

Cystic dystrophy of the duodenal wall is a rare lesion characterized by the presence of cysts within the duodenal wall that originate from ectopic pancreatic tissue. This lesion can be induced by inflammation of ectopic pancreatic tissue within the duodenal wall, secondary to obstruction of pancreatic excretory ducts.

Since the first report in 1970 by Potet and Duclert,⁴⁶⁸

Figure 34-74. Intramural duodenal hematoma after blunt abdominal trauma. CT scan shows a sausage-like cystic lesion (H) in the wall of the duodenum.

Figure 34-75. Pancreatitis with secondary duodenal involvement. CT scan shows concentric duodenal wall thickening with heterogeneous contrast enhancement of the enlarged head of the pancreas.

the radiologic appearances of this lesion have been described.⁴⁷¹ The pancreas may appear to be normal or may show evidence of chronic inflammation. In the cystic variant of cystic dystrophy, the cysts are easily demonstrated by both ultrasonography and CT between the duodenum and the pancreatic head. In contrast to a pseudocyst, the cystic variant is more frequently elongated or bilobate.⁴⁷¹ The solid variant of cystic dystrophy is depicted as thickening of the duodenal wall along with microcysts embedded within it.⁴⁷¹

Aortoduodenal Fistula

Aortoduodenal fistula is a rare and usually fatal disease. It may be primary or secondary.

The *primary* type is caused mainly by atherosclerotic aneurysms, accounting for more than 70% of cases. Other causes of aortic aneurysms complicated with aortoduodenal fistula are trauma and infections, including TB, syphilis, salmonellosis, and mycosis.⁴⁹⁹ Although extremely rare, primary aortoduodenal fistula can also occur without an associated aortic aneurysm, the causes of which include carcinomas, irradiation, peptic ulcers, foreign bodies, cholecystitis, diverticulitis, and bacterial infections.³⁰⁶

The *secondary* type generally occurs as a complication of abdominal aortic aneurysm repair. The most common sites of involvement in all types of aortoduodenal fistula are the third and fourth parts of the duodenum. Clinical symptoms include abdominal or back pain, hematemesis, melena, and an abdominal pulsatile mass. Surgical therapy carries high mortality and morbidity rates, primarily because of the difficulty and delay in establishing the diagnosis.

CT may offer a quick, inexpensive, and accurate method of diagnosis. On CT, an aortoduodenal fistula should be considered if extraluminal gas is present in the periaortic region (Fig. 34-76). Gas may also be noted within the calcified rim of the aneurysm in association with an adherent loop of intestine. Other findings include pseudoaneurysm formation and focal bowel wall thickening. In patients who have undergone aortic reconstructive surgery, com-

Figure 34-76. Primary aortoduodenal fistula in a patient with an aortic aneurysm. CT scan shows periaortic fibrosis (arrows) with subtle gas bubbles (arrowheads) in the periaortic region. The duodenal wall (D) adjacent to the aortic aneurysm is thickened, causing low-grade duodenal obstruction.

plete resolution of hematoma should occur in 2 to 3 months and no ectopic gas should be visualized at 3 to 4 weeks.⁴⁷⁶ After that time, any amount of perigraft soft tissue, fluid, or ectopic gas should be considered a sign of graft infection or aortoenteric fistula. However, the differentiation between aortoenteric fistula and perigraft infection is difficult, although the presence of ectopic gas favors the diagnosis of aortoenteric fistula.³⁵⁶

Small Intestine

Technique and Normal Anatomy

For homogeneous filling and distention of the small intestine, one should decide on the type, amount, and time sequence of oral contrast agents as well as review the patient's history or previous radiologic studies. In general, patients generally tolerate 800 to 1000 mL of dilute barium suspension with reasonable results. Collapsed or poorly opacified small-bowel loops may simulate focal wall thickening or mass lesion. In certain instances, pharmacologic agents such as metoclopramide are necessary to stimulate motility of the upper GI tract. Metoclopramide increases the tone and amplitude of gastric contractions, relaxes the pyloric sphincter and duodenal bulb, and increases peristalsis of the duodenum and the jejunum. However, this drug is contraindicated in patients with known or suspected pheochromocytoma, bowel obstruction, bowel perforation, or GI bleeding.⁴⁹²

In general, use of oral contrast agents helps in the detection of abnormalities in the small intestine, but administration of the high-density contrast agents are not necessary for certain conditions, such as suspected mesenteric ischemia or small-intestinal obstruction due to adhesions, bands, or volvulus. Such a recommendation is attributable to the absence of or poor contrast enhancement in the bowel after infusion of the IV contrast material, which is one of the most important indicators for establishing the diagnosis of strangulated obstruction²⁰⁸ or intestinal ischemia; therefore, this finding can be overlooked if high-

density contrast agents are used. Furthermore, in patients with small-intestinal obstruction, the fluid in the distended bowel already provides a good contrast agent. In performing CT in patients with blunt trauma, use of both IV and oral contrast material is necessary. The oral contrast agent must be diluted enough to avoid causing reconstruction artifacts and must be administered 20 to 30 minutes before scanning to allow for good bowel opacification. Scans must extend through the pelvis.

On CT, the normal small-bowel wall thickness measures 2 to 3 mm; a wall thicker than 4 mm is considered abnormal except in the terminal ileum, where 5 mm is considered the upper limit for normal.⁵⁰⁷ The thickness of valvulae conniventes also should not exceed 3 mm. When the intestine is collapsed or partially distended, the wall may appear to be 3 to 4 mm thick. If the wall seems to be concentrically and symmetrically thickened and is homogeneously enhanced, the clinical significance of a thickness greater than 4 mm should be interpreted cautiously and assessed in relation to the degree of distention of the small-bowel loop.¹⁹ The fat in the mesentery has the same attenuation as fat elsewhere in the body. Major arteries and veins are identifiable as branching structures within mesenteric fat and do not exceed 3 mm in diameter.²⁶³ Mesenteric lymph nodes are occasionally observed within mesenteric fat and do not exceed 3 mm in diameter.

Neoplasms

Although the small intestine represents about 75% of the total length of the GI tract and more than 90% of its total mucosal surface, it is the site of fewer than 25% of all GI neoplasms and fewer than 2% of all malignant neoplasms.⁶²⁴ The most common histologic types of benign small-intestinal tumors are benign stromal tumor, lipoma, and adenoma, whereas malignant tumors include adenocarcinoma, carcinoid tumor, lymphoma, and malignant stromal tumor.

The nonspecific nature of symptoms contributes to the delayed diagnosis of small-intestinal tumors, generally resulting in the poor prognosis of these patients. Even though barium studies, such as enteroclysis, and small-bowel follow-through examinations have been used as primary diagnostic methods, CT and MRI not only have become a primary tool in cases with a palpable mass, small-bowel obstruction, or known lymphoma but also play a large role in preoperative staging and follow-up. According to a study that analyzed 35 patients with small-bowel neoplasms, the tumor detection rate by CT was 80%.³¹⁵ Dudiak and co-workers¹³¹ were able to suggest a specific tumor diagnosis in 60% of the patients with adenocarcinomas, 58% of patients with lymphomas, and 33% of those with carcinoid tumors and malignant stromal tumors. CT is helpful in staging the small-bowel malignancy, but their reported accuracy was not high (47%) in a series that included 15 patients with small-bowel adenocarcinoma.⁶⁶

Adenocarcinoma

Primary adenocarcinoma of the small intestine is rare, accounting for approximately 40% of malignant tumors of the small intestine. When this lesion occurs, it generally

Figure 34-77. Primary jejunal carcinoma. *A*, CT scan shows bowel obstruction (*arrowheads*) at the site of the tumor. *B*, On small-bowel follow-through, a polypoid mass (*arrows*) and luminal narrowing are seen in the jejunum along with proximal bowel loop dilatation.

arises in the proximal jejunum. Risk factors for the development of small-bowel adenocarcinoma include a history of Crohn's disease, sprue, Peutz-Jeghers syndrome, Lynch syndrome II, congenital bowel duplication, ileostomy, or duodenal or jejunal bypass surgery. The most frequent gross types are infiltrative, resulting in early bowel obstruction, and ulcerative, as represented by bleeding. Polypoid forms are uncommon.

Adenocarcinomas tend to metastasize early to regional lymph nodes and to invade the mesenteric vessels when they are located near the mesenteric root. On CT scans, the tumor appears as an eccentric focal mass or a circumferential bowel wall thickening in a short segment (Figs. 34-77 and 34-78). Narrowing of the lumen and dilation of the proximal bowel are also common. However, tumors smaller than 2 cm in diameter may be missed by CT and are better detected by barium study.³¹⁵

Carcinoid

After the appendix, the small bowel is the second most frequent site of carcinoid tumors, representing up to 20% of GI carcinoids. Ninety percent of these tumors are located in the ileum. Carcinoid tumors vary in appearance from a small submucosal lesion to a large intraluminal ulcerating lesion. The tumor tends to infiltrate the mesentery, causing characteristic desmoplastic mesenteric reactions such as angulation, kinking, rigidity, and separation of small-bowel loops.

Despite widespread metastases, the primary tumor itself may be difficult to detect on CT and even at laparotomy owing to its small size. Therefore, some researchers advocated the use of scintigraphy using meta-iodobenzylguanidine (mIBG) labeled with iodine 131 as a screening procedure in patients thought to have carcinoid tumors.³ The *carcinoid syndrome*, which includes diarrhea, flushing, and

Figure 34-78. Primary jejunal adenocarcinoma. *A*, Coronal true fast imaging with steady-state precession (FISP) MR image shows a high-signal-intensity mass (*arrowheads*) obstructing the small-bowel loop. *B*, Gadolinium-enhanced MR image shows a high-signal-intensity mass (*arrows*) at the site of bowel obstruction.

Figure 34-79. Carcinoid tumor. CT scan shows an intramural mass (C) in the bowel loop near the ileocecal region. Visualization of the primary carcinoid tumor is unusual. (From Megibow AJ, Balthazar EJ: *CT of the Gastrointestinal Tract*. St. Louis, CV Mosby, 1986.)

abdominal pain, occurs in 2% of cases of small-bowel carcinoid, but it is much more likely to be present in cases of hepatic metastasis.⁵⁵⁸ CT may show virtually pathognomonic features, with a mesenteric mass associated with radiating linear or curvilinear soft tissue strands (Figs. 34-79 and 34-80). Calcifications are seen in approximately 70% of cases with mesenteric carcinoid tumor.⁴⁴⁹ The occurrence of retroperitoneal lymphadenopathy is not rare.⁴⁶⁵ CT features of small-bowel carcinoid tumor may be similar in appearance to those of lymphoma, metastasis, Crohn's disease, and mesothelioma.

Gastrointestinal Stromal Tumor

Stromal tumors are usually solitary, benign tumors that are categorized by their differentiation into smooth muscle or neural tissue. Tumors are classified as (1) benign, (2) borderline, or (3) malignant.

Figure 34-80. Mesenteric changes in a carcinoid tumor. Stellate, centripetally oriented, thickened mesenteric vessels are seen subtending a dilated, "kinked" loop of distal ileum (arrows). The primary tumor is not visualized. (From Megibow AJ, Balthazar EJ: *CT of the Gastrointestinal Tract*. St. Louis, CV Mosby, 1986.)

In contrast to benign stromal tumors (leiomyomas) that occur anywhere in the small intestine, malignant stromal tumors (leiomyosarcomas) arise more commonly in the ileum than in the jejunum. Symptoms depend on the growth pattern, that is, submucosal, subserosal, or intraluminal.

On CT and MRI, this tumor appears as a large, heterogeneous mass with central necrotic areas, often growing in an exoenteric pattern with a large extraluminal component (Figs. 34-81 and 34-82). Severe hemorrhage within the mass, which is associated with hypervascular stromal tumors, produces a fluid-fluid level. Calcification is occasionally demonstrated.⁹³ Those tumors, located in the pelvis, often resemble ovarian neoplasms. The differentiation between benign and malignant stromal tumors is radiologically difficult, but CT findings favoring malignant stromal tumor include a large mass greater than 5 cm, lobulated contour, heterogeneity with central necrosis or liquefaction, mesenteric infiltration, regional lymphadenopathy, and exophytic growth.⁹³ Metastasis occurs by direct extension and by the hematogenous route. However, intraperitoneal spread (peritoneal leiomyosarcomatosis) may occur by intraperitoneal seeding via ascitic fluid or by embolic metastases.⁴⁰⁵

CT manifestations of leiomyosarcomatosis mimic those of peritoneal carcinomatosis, except for a much lower incidence of ascites and lymphadenopathy (see Fig. 34-82).⁵⁹⁰ Hepatic metastasis may appear almost cystic on CT.

Lymphoma

Lymphoma accounts for approximately 20% of all small-bowel tumors. The small intestine closely follows the stomach as the most frequent site of disease, and multicentric involvement occurs in 10% to 25% of cases.³⁴⁵ Almost all small-bowel lymphomas are non-Hodgkin's lymphoma; most of them are of B-cell origin, but the cases complicating celiac disease are of T-cell origin. Predisposing conditions include AIDS, celiac disease, systemic lupus erythematosus (SLE), Crohn's disease, and chemotherapy.³⁴ In children and young adults, lymphoma primarily affects the ileocecal region; in adults, the distal ileum is the most

Figure 34-81. Malignant gastrointestinal stromal tumor of the ileum. Oblique coronal T2-weighted half-Fourier acquisition single-shot turbo spin-echo (HASTE) (A) and axial T2-weighted (true fast imaging with steady-state precession [FISP]) (B). MR images show a mass (arrows) with a lobulated surface in the ileum. High signal intensity within the mass indicates tumoral necrosis.

frequent site of tumor.³⁴⁵ In lymphoma complicating celiac disease, however, the proximal jejunum is usually involved.

Although the CT appearance of lymphomas is variable, these tumors can be classified as follows⁵¹⁶:

1. *Circumferential* forms are characterized by concentric bowel wall thickening (Fig. 34-83). Aneurysmal dilatation of the lumen, which is regarded as one of the most characteristic features of the lymphoma, occurs in approximately 50% of cases.^{131, 315} Except for cases with developing intussusception, bowel obstruction is rare

because the tumor weakens the muscularis propria of the bowel wall and does not elicit a desmoplastic response.⁵¹⁶

2. *Cavitary* forms are the second most commonly occurring pattern (Fig. 34-84). Cavitation of the tumor bulk results from ulceration of the mucosa with extension to the intramural portion of the tumor. Compared with stromal or epithelial tumors, the lymphomatous mass characteristically shows poorer contrast enhancement. Perforation of the tumor may occur secondary to a lack of desmoplastic response to tumor growth, as a

Figure 34-82. Leiomyosarcomatosis and hepatic metastasis in a malignant gastrointestinal stromal tumor of the jejunum. A, CT scan shows a large, exophytically growing cavitary mass (T) in the jejunum. Note multiple peritoneal nodules (arrowheads). B, CT scan shows a large hepatic metastatic lesion (M) and peritoneal nodule (arrows) in the omentum.

Figure 34-83. T-cell lymphoma involving the jejunum. *A*, Oblique coronal T2-weighted half-Fourier acquisition single-shot turbo spin-echo (HASTE) MR image shows multiple intramural nodules and bowel wall thickening (*asterisks*) in the jejunum. *B*, Gadolinium-enhanced coronal MR image clearly depicts lymphomatous involvement in the jejunal loop.

result of rapid tumor growth, or as a response to therapy (Fig. 34-85).²²⁴ Fistulization to the skin, solid organs, or bladder develops in 5% to 15% of cases.⁶⁵

3. **Mesenteric forms** are usually manifested as diffuse lymphadenopathy in the mesentery as well as in the retroperitoneum. A “sandwich” appearance is demonstrated when mesenteric masses surround mesenteric vessels but leave intact a thin rim of preserved perivas-

cular fat. The small-bowel loops are displaced, focally invaded, or occasionally obstructed by mesenteric masses. Mesenteric lymphoma may also appear as an ill-defined confluent mass engulfing and encasing multiple

Figure 34-84. Small-bowel lymphoma of B-cell origin with a large cavitary mass (*M*) arising from the ileum.

Figure 34-85. Perforated small-bowel lymphoma after chemotherapy. On CT scan, the bowel wall involved with lymphoma is focally perforated (*arrow*) along with evidence of a large amount of ascites and diffuse omental infiltration.

loops of adjacent bowel or as a conglomerate mantle of mesenteric tissue.

MRI appears comparable to CT in demonstrating the morphologic changes in the GI tract as well as in the peritoneal cavity in patients with small-bowel lymphomas. Contrast-enhanced MRI had an advantage in depicting the submucosal tumor location by demonstrating a three-zone appearance: (1) a high-intensity mucosa, (2) an intermediate-intensity submucosal tumor infiltration, and (3) a low-intensity proper muscular layer.⁹¹

The prevalence of lymphomas has been reported to be increased in patients with AIDS or in post-transplantation patients. In nearly all cases, the pathologic type is non-Hodgkin's lymphoma. The CT appearance of lymphoma in these immunocompromised hosts is indistinguishable from that of lymphoma in nonimmunocompromised patients.

Metastases

Metastatic disease in the small intestine may spread by:

1. Intraperitoneal seeding (ovary, stomach, appendix, colon).
2. Direct invasion from contiguous tumor (colon, pancreas, kidney, ovary, uterus).
3. Hematogenous dissemination (breast, lung, melanoma).

Intraperitoneal Seeding

Intraperitoneal seeding produces ascites, and the ascitic fluid facilitates spread throughout the abdomen. Because of gravitational flow, the peritoneal implants tend to occur in four major areas: (1) the rectouterine or rectovesical pouch, (2) the lower small-bowel mesentery near the ileocecal valve, (3) the sigmoid mesocolon, and (4) the right paracolic gutter.

Direct Invasion

In the small intestine, the tumor cells are implanted on the mesenteric border of the bowel, causing a direct bowel wall invasion. Once the bowel wall becomes involved, the tumors tend to spread circumferentially and longitudinally through the submucosa or subserosa in a short or long length, occasionally producing a linitis plastica pattern of bowel wall thickening. In such cases, the target sign is commonly seen in the thickened bowel wall.²⁰⁵ Malignant intestinal obstruction is also caused by recurrent tumor or by peritoneal carcinomatosis. The presence of a mass at the obstructed or prior surgical site or lymphadenopathy on CT favors the diagnosis of malignant rather than benign intestinal obstruction.²¹⁵ However, differentiating each condition is difficult in cases of intestinal obstruction without a demonstrable peritoneal mass. Other ancillary CT findings, such as omental infiltration, nodules or cakes, and peritoneal thickening, are also helpful in suggesting the diagnosis of peritoneal carcinomatosis.

Hematogenous Dissemination

In hematogenous dissemination of tumor to the small bowel, the involved sites are often multiple (Fig. 34–86).³⁹² The incidence of small-bowel metastasis from lung cancer is reported to be approximately 11% of cases.³⁹² In such

Figure 34–86. Hematogenous metastasis to the small intestine from sigmoid colon carcinoma. Multiple hypoattenuated nodules (arrows), noted in the dilated small intestinal loop, were confirmed to be metastatic neoplasm on surgery.

cases, the presenting symptom may be bowel perforation, intestinal obstruction, malabsorption, or hemorrhage³³⁰; perforation is caused by tumor necrosis, obstruction by bulky tumor, hemorrhage by ulcerative lesions, and malabsorption by extensive involvement of mucosal surface. When metastatic tumor is found unexpectedly at laparotomy for perforated viscus in a heavy smoker after the fifth decade, lung cancer should be included as one of the possible sites of primary tumors.

In metastatic lesions to the small intestine from breast cancer, a linitis plastica pattern of bowel involvement can also be seen.¹⁹⁵ Eighty percent of cases of melanoma metastatic to the GI tract involve the small bowel or mesentery. The site of hematogenously seeded tumor cells influences their radiologic appearance. On CT scans, metastatic melanoma may manifest as mucosal or submucosal masses, serosal implants, or carcinomatosis (Fig. 34–87).²⁸⁰ Mucosal mass may often lead to intussusception. Necrosis and ulceration may occur in large submucosal masses, but obstruction is less frequent. Lymphatic spread is less common, but when it occurs lymphadenopathy may be marked.³⁹⁰

Benign Neoplasms

Five neoplasms, making up 95% of benign small-bowel tumors include benign stromal tumors, lipomas, adenomas, fibromas, and hemangiomas.¹¹⁰

Lipomas are slow-growing tumors composed of well-differentiated adipose tissue surrounded by a fibrous capsule. They are usually solitary, but small-bowel lipomatosis has been reported.⁴⁴⁰ Of lipomas, 90% to 95% are submucosal and tend to prolapse into the bowel lumen. Lesions larger than 2 cm in diameter produce abdominal pain, diarrhea, constipation, or blood loss when the overlying mucosa is ulcerated, or intestinal obstruction develops secondary to intussusception.⁵⁶⁸

On CT, the diagnosis can be easily made by the tumor's characteristic fatty CT attenuation (Fig. 34–88). MRI is also useful in diagnosis because lipomas appear hyperintense on T1-weighted images. Focal area of soft tissue

34-87. Metastatic melanoma to the jejunum. CT scan shows a large cavitary mass at the left upper quadrant. (From Megibow AJ: *Computed Tomography and Magnetic Resonance Imaging of the Whole Body*. St. Louis, CV Mosby, 1994.)

attenuation may be occasionally seen on CT scans in a lipomatous mass, especially in cases with intussusception. This finding may be caused by focal ischemic change and does not indicate liposarcoma. Multiple hemangiomas have been reported to involve the bowel and represent an important diagnostic consideration in patients with hemangiomatosis of the lower extremity. Phleboliths are frequently detected within hemangiomatous masses, providing a clue to their nature.⁴²¹

Apart from these five benign neoplasms, inflammatory fibroid polyps can develop in the small intestine, especially at the ileum in 70% of cases (Fig. 34-89). They originate primarily in the submucosa and are composed of fibroblasts, blood vessels, and inflammatory cells within an edematous and collagenous stroma. Most of the lesions are solitary and large, often causing bowel obstruction due to intussusception. No distinctive radiologic features have been noted between these tumors and other mural or intraluminal lesions.

Figure 34-89. Intercolic intussusception due to inflammatory fibroid tumor of the ileum. CT scan shows a heterogeneous mass in the right-sided colon with interposed mesenteric fat (arrowheads) and vessels (arrows). A round mass (M) is seen at the lead point.

Inflammatory Conditions

Intestinal Tuberculosis

By the middle of the 20th century, intestinal TB had declined dramatically; since the mid-1980s, however, the incidence of TB has increased, especially in urban areas, owing to AIDS. Intestinal TB occurs at any age and is equally prevalent in men and women. The chest radiograph may show active disease in only about 20% of patients with intestinal TB.

Intestinal TB may arise by several mechanisms³⁷⁵:

1. Swallowing of infected sputum in active pulmonary TB.
2. Ingestion of contagious milk.
3. Hematogenous spread.
4. Direct extension from adjacent organs.

After the tubercle bacillus enters the GI tract, it traverses the mucosa to lodge in the submucosa. Lymphangitis, endarteritis, and fibrosis ensue, leading to mucosal ulceration, caseating necrosis, and narrowing of the intestinal tract.

Figure 34-88. Multiple lipomas in the small intestine. A and B, CT scan shows multiple lipomas (arrows) in the small-bowel loops.

Intestinal TB manifests three gross pathologic types: (1) ulcerative, (2) hypertrophic, and (3) ulcerohypertrophic. The highest incidence of abdominal TB has been noted in the GI tract and in the peritoneum, followed by the mesenteric lymph nodes.¹ The affinity of the tubercle bacillus for lymphoid tissue and areas of physiologic stasis may be reasons that the ileocecum is the most common site of disease.³⁷⁵

There have been limited citations in the literature describing the CT features of intestinal TB. In our experience, however, CT is useful in determining the extent of disease, in detecting its complications, and for differentiating it from Crohn's disease. The common CT finding of tuberculous enteritis is bowel wall thickening, with a range of 1 to 2 cm in thickness (Fig. 34-90).²⁰⁹ The thickened bowel may show homogeneous attenuation on CT, but mural stratification may be rarely seen. Multiple sites of involvement with skipped areas are common. Therefore, there seems to be no specific CT features of bowel wall involvement patterns in intestinal TB that can distinguish them from Crohn's disease.

Bowel loop separation can be caused by mesenteric lymphadenopathy or lymphadenitis, bowel wall thickening, intraperitoneal fluid collection, and, rarely, fibrofatty proliferation in the mesentery. Although not always the case, lymph nodal involvement patterns differ from those of Crohn's disease. The enlarged lymph nodes are commonly larger than 1 cm, may have low attenuation center caused by caseating necrosis, commonly involve the peripancreatic nodal chains, and may contain calcification (Fig. 34-91).²⁰⁶ The incidence of peritonitis in patients with intestinal TB has not been well described, but the presence of peritonitis on CT scans may favor the diagnosis of TB rather than Crohn's disease when the differentiation between the two diseases should be made.^{206, 371}

The CT findings of tuberculous peritonitis may mimic those of peritoneal carcinomatosis, including diffuse omental and mesenteric infiltration and nodules, peritoneal thickening, and ascites.²⁰⁶ In addition, the incidence of splenic

Figure 34-90. Intestinal tuberculosis. CT scan shows heterogeneous bowel wall thickening (arrows) of the ileum. The ileal loops are dilated (asterisks) as a result of bowel obstruction caused by strictures (not shown).

Figure 34-91. Abdominal tuberculosis with mesenteric lymphadenitis. Diffusely enlarged lymph nodes with central hypoattenuation (asterisks) are noted in the mesentery. (From Ha HK, Jung JJ, Lee MS, et al: CT differentiation of tuberculous peritonitis and peritoneal carcinomatosis. *AJR Am J Roentgenol* 167:743-748, 1996.)

involvement is common in abdominal TB, which includes splenomegaly, hypoattenuated nodules, or calcifications.²⁰⁶

Although intestinal TB is a chronic disease, acute onset of abdominal symptoms may develop owing to their complications. A broad spectrum of complications include intestinal obstruction, bowel perforation, fistula, GI bleeding, enterolithiasis, venous thrombosis, and traction diverticula (Fig. 34-92).^{45, 375} Intestinal obstruction is the most common complication of tuberculous enteritis, with an incidence of 12% to 60% of patients.³⁷⁵ The mechanisms may include inflammatory thickening of the bowel wall, especially in cases of hypertrophic or ulcerohypertrophic type with a long length of stricture or multiple areas of involvement and intraperitoneal adhesion.²⁰⁶ This complication commonly occurs during the medical therapy. Healing by cicatrization in the course of antituberculous therapy increases the tendency to result in obstruction, and the use of modern chemotherapeutic agents, such as rifampicin, also plays a partial role in producing cicatrization.⁹

Single or multiple bowel perforation may occur in patients with ulceration proximal to the obstruction²⁰⁶; although it may be confined to a localized area when preexisting adhesive change is present. The incidence of fistula formation is lower than that in Crohn's disease but may result from bacterial invasion of the necrotic area in the bowel, a penetrating abscess, or sequelae of the confined perforation.⁴⁵²

Crohn's Disease

Crohn's disease is a chronic transmural inflammation that may involve any part of the alimentary tract, from the mouth to the anus. One fourth to one third of patients present before age 20 years, and about 15% of patients experience an onset after 50 years of age. In the older age group, in contrast to younger people, the disease predominates in women, who show a higher frequency of colonic involvement than men. The most common sites of involvement include the distal small bowel and the proximal colon;

Figure 34-92. Bowel perforation in a patient with intestinal tuberculosis during medical therapy. *A*, CT scan shows a stricture (arrowheads) at the site of low-grade small-bowel obstruction. *B*, CT scan shows pneumoperitoneum (arrowheads) due to bowel perforation from the ulcer at the bowel loop proximal to the stricture. *C*, CT scan at a lower level shows an enterolith in the bowel proximal to the stricture.

the ileocecal area involvement occurs in approximately 50% of patients, the small bowel alone in 30% to 40%,⁴³⁴ and the colon alone in 20% to 27%.⁷⁷

An increased risk of small-bowel adenocarcinoma is likely to be present in patients with Crohn's disease, and the risk factors include Crohn's disease with duration of 20 years or longer, intestinal bypass surgery, and chronic enteric fistula.¹⁹⁸ An excessive rate of lymphomas has also been reported.¹⁹⁷ Other extraintestinal complications include hepatitis, pericholangitis, hydronephrosis, renal calculi, and gallstones. Recurrence of small-intestinal Crohn's disease depends on the preoperative disease distribution and severity and on the extent of resection. The disease recurs in 40% to 80% of patients following ileocecal or ileocolic resection, almost always in the neoterminal ileum and within 2 years.⁶²¹

CT yields accurate information regarding the extent of inflamed segment of the bowel, and it can detect potential complications. Accordingly, CT may sometimes play a critical role in the management of patients with Crohn's disease; in one study of 80 patients with Crohn's disease, CT demonstrated unsuspected abnormalities that altered medical or surgical management in 28% of cases.¹⁵⁸

Although CT scans are usually normal when the disease is limited to the mucosa, the most common CT finding in Crohn's disease is bowel wall thickening ranging from 1 to 2 cm (Fig. 34-93).¹⁹² The presence of mural stratification (double-halo or target sign) in thickened wall on CT may

indicate an acute phase of disease,^{183, 190} and this CT finding appears to be caused by submucosal edema or fat infiltration.⁶⁰³ With the development of long-standing disease and transmural fibrosis, the thickened wall becomes homogeneous in attenuation. The distribution of bowel involvement is commonly segmental with interposed loops of normal bowel.

Figure 34-93. Crohn's disease. CT scan shows uneven, concentric bowel wall thickening (asterisks) of the small intestine.

A variety of conditions cause bowel loop separation or abdominal mass on small-bowel follow-through examination, and CT is useful in determining their primary causes. These causes are as follows:

- Abscess
- Phlegmon
- Fibrofatty proliferation within the mesentery
- Thickened bowel wall
- Mesenteric lymphadenopathy

Abscesses occur in about 15% to 20% of patients with Crohn's disease owing to sinus tracts, fistulas, perforations, or postsurgical complication.³⁰² On CT, they appear as a low-attenuation mass with a thick wall that may enhance with administration of IV contrast material, but the most specific finding may be the presence of gas bubbles within the mass (Fig. 34-94). CT is also useful for guiding percutaneous drainage of abscess collection, frequently obviating the need for surgical intervention.

A *phlegmon* produces a loss of definition of surrounding organs and a smudgy or streaky appearance of the adjacent mesenteric or omental fat.

Fibrofatty proliferation may present as an increase in the volume and attenuation of mesenteric fat on CT along with mild mesenteric lymphadenopathy and hypervascularity within the mesentery.⁴⁰⁴

Mesenteric lymphadenopathy is a common finding in

Figure 34-95. Crohn's disease. CT shows diffuse bowel wall thickening (asterisks) of the small intestine with a skipped segment. Minimal lymphadenopathy is seen in the mesentery.

patients with Crohn's disease, but lymph node sizes usually range from 3 to 8 mm (Fig. 34-95). When the lymph nodes are larger than 1 cm, the presence of lymphoma or carcinoma as a complication of Crohn's disease must be excluded.⁵⁴¹ Fistula and sinus tracts are hallmarks of Crohn's disease, occurring in about one third of patients.¹⁸³ Barium study may be limited in the identification of the

Figure 34-94. Peritoneal abscess complicating Crohn's disease. A, Coronal T1-weighted (2D fast low-angle shot [FLASH]) MR image shows a heterogeneous mass (arrows) in the peritoneal cavity. B, Coronal gadolinium-enhanced MR image clearly depicts multiseptated abscess cavity (arrows) with well-enhanced thick peripheral wall and internal septations.

Figure 34-96. Enterocutaneous fistula in a patient with Crohn's disease. CT scan shows a fistulous tract (arrowheads) and bowel wall thickening of the ileal loop.

origin, anatomic course, and site of communication of fistula and sinus tract, but CT may have an advantage in demonstrating their full extent (Fig. 34-96). In some instances, CT scans may show hypervascularity of the involved mesentery, producing vascular tortuosity, dilatation, prominence, and wide spacing of the vasa recta in a comblike manner (*comb sign*) (Fig. 34-97).⁴⁰⁴ The presence of hypervascularity may suggest an acute exacerbation.⁴⁰⁴

MRI has been reported to be useful for demonstrating the intestinal and extraintestinal changes of Crohn's disease involving the GI tract (Fig. 34-98; see also Fig. 34-97).^{210, 355} According to Shoenut and associates,⁵⁴⁰ bowel wall thickness, length of diseased segment, and amount of enhancement with gadolinium correlated with disease activity.

Mycobacterium avium-intracellulare Enteritis

Mycobacterium avium-intracellulare (MAI) is the most common cause of systemic bacterial infection in patients with AIDS. It frequently affects the GI tract as well as the hepatobiliary system.⁶¹⁷ Patients typically present with progressive weight loss, watery diarrhea, malabsorption, fever, and chills. This disease is often called *pseudo-Whipple's disease* because of the clinical, histologic, and radiologic similarities.⁴⁶⁷

The single most sensitive test for the diagnosis of disseminated MAI is the peripheral blood culture, with a reported sensitivity of 86% to 98%.⁶¹⁷ CT may demonstrate bowel wall thickening especially in the jejunum (Fig. 34-99). The presence of low-attenuation mesenteric and retroperitoneal lymphadenopathy is characteristic. Unlike other infectious processes, the nodes in MAI infection are often bulky and may be impossible to distinguish from lymphoma.²⁴³ Hepatosplenomegaly may be seen.

Eosinophilic Enteritis

Eosinophilic gastroenteritis is a rare inflammatory disorder characterized by focal or diffuse infiltration of the GI tract by eosinophils. It usually occurs during the third decade of life. Although the etiologic mechanism is unknown, an allergic or immunologic disorder is the most commonly proposed cause for this disease.⁵⁸⁹ Peripheral eosinophilia (present in 60% to 96% of patients) is regarded as one of the most important clinical features for diagnosis.^{303, 424} An allergic disorder such as bronchial asthma, food allergy, eczema, or atopic dermatitis occurs in approximately 50% of patients.³⁰³ The clinical response to steroid treatment is usually dramatic.

The *Klein classification*³⁰³ separates eosinophilic gastro-

Figure 34-97. Crohn's disease. A, T1-weighted MR image shows mesenteric lymphadenopathy (arrows), especially along the jejunal branches of the mesenteric artery. Note the bowel wall thickening (arrowheads) of the ascending colon. B, Coronal true fast imaging with steady-state precession (FISP) MR image shows fibrofatty proliferation (M) with hypervascularity ("comb sign") of mesenteric vasculatures. Also note the focal bowel wall thickening (arrows) and pseudosacculation along the antimesenteric border of the adjacent bowel loop.

Figure 34-98. Crohn's disease with stricture. A, Coronal half-Fourier acquisition single-shot turbo spin-echo (HASTE) MR image shows irregular concentric bowel wall thickening and luminal narrowing (arrows) with diffuse inflammatory infiltration in the perienteric region. Bowel wall thickening is also present along the mesenteric border of the dilated small-bowel loop (asterisks). B, Multiplanar reconstruction images have the advantages of easy orientation of bowel wall and perienteric changes such as stricture (arrows), bowel wall thickening (arrowheads), and mesenteric infiltration (asterisks). (From Ha HK, Lee EH, Lim CH, et al: Application of MRI for small intestinal diseases. *J Magn Reson Imaging* 8:375-383, 1998.)

Figure 34-99. *Mycobacterium avium-intracellulare* enteritis. CT scan shows concentric bowel wall thickening (asterisks) of the small-bowel loops with evidence of bowel dilatation and fold thickening. Mesenteric lymphadenopathy (arrows) is also seen. (Courtesy of K. C. Cho, M.D., Newark, New Jersey.)

enteritis into three groups according to the predominant tissue layer of involvement in the GI tract:

- Predominant mucosal disease
- Predominant disease of the muscularis
- Predominant subserosal disease

Patients usually present with recurrent episodes of abdominal pain, vomiting, diarrhea, or malabsorption, but the clinical features depend on the location and depth of tissue involvement.

Mucosal involvement leads to protein-losing enteropathy, fecal blood loss, and malabsorption.

Involvement of muscle layer (*muscularis*) often causes obstruction of the gastric outlet or small bowel, and subserosal involvement manifests as eosinophilic ascites. The stomach and small bowel are most frequently affected; the stomach alone is involved in approximately 40% of cases, both the stomach and small bowel in approximately 50%, and the small bowel alone in about 10%.⁴²⁴ However, the colon and esophagus may also be involved. The most common CT features include circumferential bowel wall thickening in the distal stomach and proximal small bowel (Fig. 34-100). A target appearance can be seen in the thickened wall.

When *subserosal* involvement is predominant, eosinophilic ascites, eosinophilic pleural effusions, lymphadenopathy, and diffuse omental and mesenteric infiltration may also be seen. Rarely, inflammatory mass in the involved bowel may develop, causing bowel obstruction.⁵⁴³

Giardia lamblia Infection

Giardiasis is a small-intestinal infection with the protozoan parasite, *Giardia intestinalis*. Isolates obtained from humans are commonly given the name *Giardia lamblia*. The major clinical impact of this infection is in young children in whom it can produce persistent diarrhea, intestinal malabsorption, and retardation of growth and development. Outbreaks have been linked to contaminated water

supplies and situations involving person-to-person contact. Immunocompromised patients are especially at risk.

Most cases can be diagnosed by a single stool examination. CT findings show thickening of the wall of the duodenum and jejunum and mesenteric lymphadenopathy.⁴³⁸

Yersinia enterocolitica Infection

Yersinioses are primarily diseases of animals, but human infections are recognized with increased frequency all over the world. In humans, the alimentary tract is probably the portal of entry in most cases. The proposed modes of infection are (1) intake of contaminated food, (2) contact with infected animals, and (3) person-to-person transmission. Enteric infection causes mucosal ulcerations in the terminal ileum, necrotic lesions in Peyer's patches, and enlargement of mesenteric lymph nodes.

Although most patients are younger than 5 years of age, the clinical presentations vary with age, sex, and immunologic state of the host: acute enteritis (<5 years of age), mesenteric adenitis (5 to 15 years of age), acute terminal ileitis (10 to 20 years of age), gastroenteritis, erythema nodosum, and polyarthritis (adults).¹⁵¹ Most cases are self-limited, but complications have included appendicitis, diffuse ulceration and inflammation of the small intestine and colon, intestinal perforation, peritonitis, ileocolic intussusception,²⁴⁹ toxic megacolon, mesenteric venous thrombosis, and gangrene of the small bowel.¹⁰³

A definitive diagnosis can be made by the isolation of *Yersinia enterocolitica* together with the demonstration of a rising antibody titer.⁵⁸⁷ The terminal ileum is most commonly affected in a length approximately 10 to 20 cm. The most typical lesions consist of shallow, small, round aphthoid ulcers to longitudinal ulcers of 2 cm or more, resembling those seen in Crohn's disease. CT may help to detect bowel wall thickening of the distal ileum as well as enlarged mesenteric lymph nodes (Fig. 34-101).

Salmonellosis

Salmonellosis is one of the common causes of acute gastroenteritis. *Salmonella* species are gram-negative non-spore-forming bacilli, and in humans the disease is usually contracted by ingestion of contaminated foods, notably meat, dairy products, poultry, and eggs. Susceptibility to infection is heightened in patients with sickle cell anemia, hemolytic disease, and immunodeficiency. The terminal ileum may be mainly affected, although colonic changes are also seen. *Salmonella* organisms penetrate the wall of the small bowel, invading the lymphoid tissue of Peyer's patches with development of small, longitudinally oriented ulcers. Ileal inflammation is usually superficial and involves the mucosa and lamina propria. Once the patient recovers, intestinal lesions heal with minimal fibrosis so that stricture formation is unusual.

CT findings include circumferential and homogeneous thickening of the terminal ileum over a segment of 10 to 15 cm (Fig. 34-102).²¹ The colonic wall can also be mildly thickened. Small-bowel perforation with peritonitis may occasionally occur.¹⁶⁸

Whipple's Disease

Whipple's disease is a chronic, multisystemic condition resulting from a systemic infection with *Tropheryma whip-*

Figure 34-100. Eosinophilic gastroenteritis. **A**, CT scan shows diffuse thickening (*asterisks*) of the small intestine with ascites. **B**, Coronal T2-weighted half-Fourier acquisition single-shot turbo spin-echo (HASTE) MR image clearly depicts the discontinuous bowel wall involvement as well as bowel wall thickening (*arrows*) and ascites. **C**, Coronal gadolinium-enhanced MR image shows a target appearance of the thickened bowel wall with a markedly enhancing middle layer (*arrows*).

pell. It frequently involves the jejunum and ileum but usually spares the duodenum. There is a characteristic infiltration of the small-bowel mucosa and submucosa with foamy macrophages containing periodic acid-Schiff-positive glycoprotein granules.¹⁶¹ The villi appear blunted and distorted by collections of foamy macrophages. Widespread fatty deposits and granulomas are present in the intestinal mucosa and intra-abdominal lymph nodes, reflecting lymphatic obstruction with fatty extravasation. The most common clinical presentation is a generalized malabsorption syndrome.

CT shows diffuse thickening of the small-bowel folds. Characteristically, the mesenteric or retroperitoneal nodes are of low CT attenuation owing to fatty deposits.³⁰³ Ancillary CT findings include hepatosplenomegaly and ascites.

Lymphangiectasia

Intestinal lymphangiectasia, characterized by protein-losing enteropathy, hypoproteinemia, edema, malabsorption, and dilated lacteals, is a rare congenital obstructive defect of the lymphatics affecting primarily children and young adults. Hypoplastic visceral lymphatics obstruct lymph flow, causing increased intestinal lymphatic pressure and thereby dilating lymphatic vessels through the small bowel and mesentery. Hypoproteinemia and steatorrhea are secondary to rupture of the dilated lymphatic vessels with discharge of lymph into the bowel lumen. The condition may also develop secondary to inflammatory or neoplastic involvement of the lymphatics.¹⁶⁴

In both primary and secondary lymphangiectasia, CT

Figure 34-101. Yersiniosis. *A*, Small-bowel follow-through scan shows multiple nodular defects (arrows) in the distal ileum. *B*, CT scan shows minimal mesenteric lymphadenopathy (arrows).

shows diffuse small bowel and fold thickening.^{473, 555} A halo may be present within the wall owing to edema. The presence of mesenteric infiltration and retroperitoneal or mesenteric lymphadenopathy may suggest the secondary form because adenopathy is not usually present in the primary form.⁵⁵⁵

Mucormycosis

Mucormycosis, a relatively uncommon opportunistic fungal infection, is caused by fungi of the order Mucorales. The disease is known to occur especially in association with diabetes mellitus, leukemia, or lymphoma.⁷² When the GI tract is involved, the stomach is the most common site of involvement and the intestinal form has a predilection for the terminal ileum and cecum.³⁶¹ GI involvement usu-

ally complicates local disease processes, such as intractable peptic ulceration, amebic colitis, persistent peritonitis, and malnutrition.^{72, 329} However, a fulminant and rapidly fatal course can occur in certain instances.³⁶¹

These fungi exhibit a remarkable tendency to infiltrate the walls of blood vessels, especially arteries. They grow profusely into the vessel lumen and initiate acute vasculitis and thrombosis of major blood vessels. As a result, ischemic infarction can occur in any organ.³²⁹ In some instances, venous involvement with thrombosis causes hemorrhagic necrosis.³⁸⁵

CT studies show diffuse circumferential wall thickening of the small bowel, intermingled with areas of both intense and poor contrast enhancement (Fig. 34-103).³²² Pathologically, poorly enhanced areas coincide with the areas of necrosis and infarction, whereas intensely enhanced areas

Figure 34-102. Perforated salmonellosis. *A* and *B*, The ileal wall is diffusely thickened (asterisks) with a small amount of intraperitoneal fluid and free gas (arrows).

Figure 34-103. Intestinal mucormycosis. CT scan shows alternating areas of poor and prolonged contrast enhancement in the bowel wall of the small intestine (*asterisks*) along with regional mesenteric haziness. (From Lee JH, Ha HK, Yoo ES, et al: CT and sonographically guided biopsy in a patient with intestinal mucormycosis. *AJR Am J Roentgenol* 175:129-131, 2000.)

represent the areas of edema and hemorrhage in the submucosa and muscle layers due to congestive changes. Therefore, such CT findings can easily be confused with chemotherapy-induced necrotizing enteropathy if they have been seen in patients with lymphoma or leukemia who had received chemotherapeutic regimens.

Amyloidosis

Amyloidosis is a group of heterogeneous disorders caused by the extracellular deposition of a protein substance. Any part of the GI tract is involved, but the small intestine is most commonly affected. According to the traditional clinical classification,³¹² there are five types of amyloidosis:

- Primary
- Secondary

- Familial
- Senile
- Localized

However, use of the classification based on the histochemistry of the amyloid fibril is preferred⁵⁶²:

- Amyloid A protein (AA)
- Light chain protein (AL)
- Prealbumin (AF)
- β_2 -microglobulin (AH)

All four types of amyloid substance involve the GI tract, although each protein has its own specific mechanism of pathogenesis, radiologic findings, and clinical course. In the AL type, massive amyloid deposits commonly occur in the muscularis propria and submucosa of the intestinal wall.⁵⁶² Wide granular deposits in the lamina propria mucosa are much more commonly seen in the AA type than in the AL type.¹⁷⁸

Vascular deposits of amyloid in the submucosa are commonly seen in all types of amyloidosis. As a result, the vessel walls are thickened, and the lumen is gradually reduced and eventually occluded, leading to ischemia, ulceration, infarction, and even perforation.⁵⁶² Although focal or diffuse symmetrical wall thickening of the affected bowel is a common CT finding, CT may not differentiate infiltrative from ischemic changes (Fig. 34-104). Intestinal hypomotility results in delayed transit of the oral contrast agent.⁴⁴⁸ Adenopathy may be present but not as bulky or low attenuation as seen in Whipple's disease. Occasionally, bowel wall calcification can be seen.²⁴³

Cytomegalovirus Enteritis

CMV is a herpes virus that can be transmitted sexually or transmitted via infected organs, blood, or needles. CMV remains in a latent state in the host after the initial infection. With increasing impairment of cell-mediated immunity, particularly a CD4 lymphocyte count below 100 mm³, viral reactivation may occur.⁵⁹² Clinically evident CMV infections most commonly affect immunosuppressed patients, including transplant recipients and patients with

Figure 34-104. Amyloidosis. A, Mild bowel wall thickening is noted in the small intestine (*asterisks*). Note the small amount of ascites. B, Small-bowel follow-through scan shows nodular fold thickening (*arrows*) in both the jejunum and the ileum.

Cytomegalovirus enterocolitis. *A*, The circular folds of the ileum are diffusely thickened (*arrows*) with spastic narrowing of the lumen on a single-phase study of enteroclysis. *B*, Bowel wall at the involved segment of the ileum (*asterisk*) is minimally thickened with proximal loop dilatation. There is also diffuse concentric bowel wall thickening (*arrows*) of the rectosigmoid colon. (Courtesy of D. T. Maglinte, M.D., Indianapolis, Ind.)

AIDS; however, it may occasionally occur in nonimmunosuppressed individuals, including those with diabetes mellitus, those who receive corticosteroids or radiation therapy, and those who are elderly.⁵⁵³

Clinical manifestations usually include diarrhea, hematochezia, abdominal pain, and constitutional symptoms. Although the colon is the organ most commonly affected by CMV infection, the incidence of small-bowel involvement is not uncommon.^{420, 570}

Radiographic features include ulcers of various sizes and depth along with mucosal fold thickenings and luminal narrowing.⁵⁷⁰ The ulcers are usually numerous, round, or serpiginous, often reaching the muscular layer with subsequently common occurrence of bowel perforation; CMV inclusions in the capillaries and venules of the mucosa and submucosa may produce focal ischemias that are responsible for mucosal ulcerations.¹⁸⁶ These features simulate those of inflammatory bowel disease, bacterial or parasitic infection, ischemic bowel disease, lymphoma, and GVHD. CT may demonstrate bowel wall thickening in both the small and the large intestines, lymphadenopathy, and ascites (Fig. 34-105).⁴²⁰

Trauma

Bowel disruption due to blunt abdominal trauma is no longer rare and occurs in 5% to 25% of patients. The increasing frequency is attributed to the automobile and industrialization. The mechanisms of bowel disruption have been thought to be at least one of the following different types of stress:

1. Direct, crushing impingement of the bowel against the prominent, unyielding vertebral column.⁴³⁹
2. A tearing or shearing force at areas of the bowel where either the bowel or mesentery is relatively fixed.¹¹¹

3. A sudden increase of intraluminal pressure in a closed loop of bowel, especially the duodenum.

It is generally agreed that the segments of the small intestine most commonly involved by blunt abdominal trauma are the duodenum near the ligament of Treitz, the proximal jejunum just beyond the ligament, and the ileum just proximal to the ileocecal valve, because these segments are relatively fixed. The relationship of intestinal injury to intra-abdominal adhesions has been well documented,⁵⁹⁷ and the knowledge of a previous surgery should suggest possible intestinal damage. Similarly, fixation of the small intestine within an inguinal hernia has led to bowel perforation.¹¹¹

Different types of injuries occur in the blunt wounds of the small intestine, including transection, perforations, avulsions, intramural hematoma, and serosal tears. Delayed perforation up to 10 days after injury may occur. Clinically, the classic triad of rigidity, absent or decreased bowel sounds, and tenderness occur in approximately one third of patients.⁴⁵⁶

Diagnostic peritoneal lavage following blunt trauma markedly improves sensitivity (94% to 100%) for detection of intraperitoneal injury but remains less sensitive for the detection of retroperitoneal trauma to the duodenum, colon, and kidney.^{140, 153} Because lavage findings are nonspecific for the type or extent of organ injury, positive lavage results may lead to nontherapeutic laparotomy rates of 6% to 25% with associated morbidity.¹⁵³

Although the accuracy of CT is controversial, CT is effective in detecting bowel and mesenteric injuries caused by blunt abdominal trauma and may be useful in predicting the need for either surgical repair or conservative management.^{57, 130, 411, 506} In performing CT scan in patients with blunt trauma, use of both IV and oral contrast material is necessary. The oral contrast agent must be diluted enough to avoid causing reconstruction artifacts and must be ad-

Figure 34–106. Bowel perforation of the transverse colon and jejunum after blunt abdominal trauma. CT scan shows bowel wall thickening of both the transverse colon (*asterisks*) and the jejunal loop (*arrows*) along with diffuse pericolic and perienteric infiltration. Also note pneumoperitoneum (*arrowhead*), intraperitoneal fluid collection, and right retroperitoneal hematoma (H).

ministered 20 to 30 minutes before scanning to allow for good bowel opacification. Scans must extend through the pelvis.

On CT, injury to the bowel may be manifested by bowel wall thickening, which is seen in 75% of patients with transmural laceration.⁵⁰⁶ The two most specific CT signs of bowel injury include pneumoperitoneum and frank extravasation of oral contrast agent. Unfortunately, these findings are insensitive, with free air seen in 32% to 56% and extravasated oral contrast seen in only 12%.^{331, 506} *Note:* Intraperitoneal gas may result from causes other than bowel perforation, such as pneumomediastinum or diagnostic peritoneal lavage.

Other highly specific signs requiring surgical repair are bowel wall thickening in combination with bowel wall discontinuity,⁵⁷ abnormally intense contrast enhancement

of the bowel wall,⁴²⁵ adjacent mesenteric hematoma or infiltration,¹³⁰ and intermediate and large amounts of free peritoneal fluid (Figs. 34–106 and 34–107).⁵⁰⁶ The finding of moderate to large amounts of intraperitoneal fluid with no visible solid organ injury is also a useful sign of bowel or mesenteric injury.^{57, 332}

Mesenteric fluid is extremely uncommon in solid organ injury, and its presence should be considered highly suggestive of bowel or mesenteric injury.^{331, 425} The presence of only focal bowel wall thickening or hematoma indicates the need for close observation but not necessarily immediate surgical exploration without other definite indications.¹²⁷ Furthermore, bowel wall thickening may also occur in other conditions such as hypovolemic shock syndrome, hypoproteinemia, liver cirrhosis, inflammatory bowel, ischemia, heart failure, and incomplete bowel distention.

As demonstrated by several researchers,²³⁶ blunt abdominal trauma is also one of the causes of segmental intestinal stenosis in association with acute ischemic insult to the intestine. Focal deprivation of the blood supply secondary to a tear in the mesenteric attachment is considered to be the main cause of the development of focal segmental ischemia. Although it depends on the site of the trauma, the stricture usually occurs near the proximal or distal extremes of the small intestine where mesenteric mobility commences.³⁷³ Intestinal stenosis is characterized by the delayed onset of symptoms within a variable interval of months or years after the accident. Therefore, if a patient's history is overlooked, intestinal stenosis can be confused with other inflammatory or neoplastic GI diseases.

Radiographic features of tubular narrowing and circumferential ulcers in post-traumatic intestinal stenosis are similar to those in patients with chronic intestinal ischemia.³⁷⁰ On CT, post-traumatic intestinal stenosis shows nonspecific bowel wall thickening with or without bowel obstruction (Fig. 34–108). In such cases, barium studies of the colon or small intestine appear to be more useful than CT in demonstrating the characteristic findings of tubular or circumferential luminal narrowing in a short segment.

Figure 34–107. Blunt trauma with bowel perforation and mesenteric injury. A, Bowel perforation (*arrow*) is noted in the transverse colon with regional free gas collection (*asterisks*) and pericolic infiltrates. The jejunal wall (J) is also thickened as a result of traumatic confusion. B, The mesenteric vessels (*asterisk*) are increased and prominent with their distorted courses, which resulted from mesenteric vascular injury. Intraperitoneal collection of free gas and fluid is also seen.

Figure 34-108. Post-traumatic intestinal stenosis following blunt abdominal trauma 1 month before. *A*, Small-bowel follow-through shows short segment of tapered, circumferential luminal narrowing (arrows) of the distal jejunum along with thickened folds and ulcerations. *B*, CT scan shows marked contrast enhancement of the thickened bowel wall (arrows). Regional mesenteric vascular engorgement and haziness (asterisks) are also seen. (From Ha HK, Rha SE, Kim AY, et al: CT and MR diagnoses of intestinal ischemia. *Semin Ultrasound CT MRI* 21:40-55, 2000.)

Gastrointestinal Disease in the Immunocompromised Host: Complications after Transplantation

Human allogeneic bone marrow transplantation has been used with increasing frequency for treatment of lymphoma, leukemia, aplastic anemia, metabolic disorders of the hematopoietic system, and some metastatic disease. Preparatory regimens such as whole body irradiation and high doses of chemotherapy as well as immunosuppressive therapy can cause profound immunosuppression after bone marrow transplantation.

Apart from GVHD, a number of abdominal complications result from this immunosuppression, which include lymphoproliferative disorders, enteritis from direct radiation or chemotherapy toxicity, infective enteritis, neutropenic colitis, pseudomembranous colitis, pneumatosis intestinalis, abdominal abscess, and increased incidence of cancer.¹⁵⁰

Graft-Versus-Host Disease

GVHD is a significant complication after transplantation as a consequence of immunologic assault of donor lymphoid cells against host target organs.¹⁵⁰ It develops when tissues containing immunocompetent cells (blood products, bone marrow, or solid organs) are transferred between persons. Acute GVHD occurs within 1 day or as late as 1 to 2 months after transplantation.⁵⁷⁴ The incidence ranges from less than 10% to more than 80%.¹⁵⁰ The major target organs in acute GVHD are the immune system, skin, liver, and intestine.^{150, 574} The initial organ involved in almost all cases is the skin; hepatic and intestinal involvement usually appear several days after the rash.⁵⁷⁴ Therefore, the hallmarks of the disease include skin rash, jaundice, and profuse secretory diarrhea.^{150, 574} Pathologically, the sine qua non of acute GVHD is selective epithelial

damage of target organs.¹⁵⁰ The destruction of intestinal crypts results in mucosal ulceration that may be either patchy or diffuse. The esophagus is less commonly involved.

In acute GVHD, small-bowel follow-through studies show a combination of fold thickening and effacement of folds with a characteristic ribbon-like or tubular appearance, associated with separation of bowel loops, excess intraluminal fluid, and rapid small-bowel transit.^{160, 512} These findings are more prominent in the ileum than in the jejunum. Unusual prolonged or persistent mucosal coating also has been reported²⁷³; the cause of this finding is unknown, but it seems likely that the barium may be adherent to mucosa, to submucosa, or to pseudomembranes or trapped in sloughed mucosa. However, the same finding also can be seen in GI inflammation due to viral infection.²⁷³ Therefore, the differentiation between acute GVHD and viral enteritis is not possible on the basis of radiographic findings alone.²⁷³

Colonic changes include luminal narrowing, wall thickening, ulceration, edema, and a haustral appearance.^{160, 512} CT findings are reminiscent of radiographic findings, including luminal narrowing, diffuse wall thickening, and prolonged contrast coating in the small intestine, colon or mesentery (Fig. 34-109).²⁷²

According to a report by Donnelly and Morris,¹²⁶ who analyzed CT findings of 16 patients with acute GVHD, acute GVHD characteristically appears on CT scans as multiple, diffuse, fluid-filled bowel loops with a thin, enhancing layer of bowel wall mucosa in all their patients; a thin, enhancing layer corresponded with mucosal destruction and replacement by a thin layer of granulation tissue. Bowel wall thickening is often absent.

Although chronic GVHD was initially defined as a GVHD presenting more than 100 days after bone marrow transplantation, it can develop 40 or 50 days after trans-

Figure 34-109. Graft-versus-host disease in a patient with bone marrow transplantation. *A*, CT scan shows diffuse thickening (asterisks) of the ileum. *B*, Axial T2-weighted half-Fourier acquisition single-shot turbo spin-echo (HASTE) MR image shows thickened ileal wall (asterisks) with ascites in the pelvic cavity. *C*, Axial gadolinium-enhanced MR image shows a well-enhancing, thickened wall in the ileum (asterisks).

plantation.¹⁵⁰ Its incidence ranges from 30% to 60% of patients. As the number of long-term survivors increases, chronic GVHD has emerged as an increasingly frequent complication of allogeneic marrow transplantation. The clinicopathologic features resemble an overlap of several

collagen vascular diseases with frequent involvement of the skin, liver, eyes, mouth, upper respiratory tract, and esophagus and less frequent involvement of the serosal surfaces and lower GI tract.^{150, 542} In chronic GVHD, the distribution and histopathology of the lesions in the intesti-

nal tract differ from those of the acute form, particularly with regard to the esophagus. Esophageal involvement causes a characteristic desquamation of upper esophageal mucosa.⁵⁴² The small bowel and colonic mucosa seem to be spared in chronic GVHD.^{150, 542}

Post-transplantation Lymphoproliferative Disorders

Post-transplantation lymphoproliferative disorders (PTLDs) are an uncommon but persistent complication of solid organ transplantation. When a primary infection with Epstein-Barr virus (EBV) occurs in an immunocompetent host, a transient lymphoproliferative disorder occurs. This proliferation of infected B lymphocytes is controlled by cytotoxic and suppressive T lymphocytes. When the infected host is immunodeficient, the proliferation of B cells may not be controlled and EBV-induced PTLD can occur.⁴²³ It includes a spectrum of disease ranging from polyclonal B-cell hyperplasia to monoclonal B-cell lymphoma.

The reported incidence of PTLD varies from 12% in pancreas transplant recipients, to 9% in heart and lung transplant recipients, and to 1% to 2% in renal and liver transplant recipients.^{357, 482} Early diagnosis of PTLD is important because reduction or cessation of immunosuppression results in tumor regression. The anatomic region of the transplant organ was the most common site of involvement in lung and liver transplant recipients.⁴⁶³

According to a series that analyzed 51 patients with PTLD,⁴⁶³ CT manifestations of non-Hodgkin's lymphoma occurring in the general population and PTLD in transplant recipients demonstrated important differences. The most striking distinction was the relatively high frequency of extranodal disease (81%) and lower frequency of nodular disease (22%) in patients with PTLD; in contrast, extranodal disease occurred in approximately 25% of nonimmunosuppressed patients with non-Hodgkin's lymphoma.⁵⁵

On CT, PTLD is similar in appearance to those of non-Hodgkin's lymphoma when solid abdominal organs and hollow viscus are involved (Fig. 34-110). The most com-

Figure 34-110. Post-transplantation lymphoproliferative disorder. Unenhanced CT scan shows an ill-defined mass in the transplanted kidney (m), which appeared as a heterogeneous mass lesion on ultrasound examination. Another mass (asterisk) is noted along the ureteral course.

Figure 34-111. Pneumatosis (arrowheads) in the right-sided colonic wall after renal transplantation. The patient showed no clinical signs or symptoms of bowel necrosis.

mon sites of involvement are the liver, small bowel, and kidney, but virtually any organ or space within the abdomen and pelvis can be affected. Although the CT appearance of GI involvement in PTLD mimics that of lymphoma, PTLD has a propensity for ulceration and perforation of the alimentary tract.⁴⁶²

Pneumatosis Intestinalis

Pneumatosis intestinalis can develop after transplantation. Contributing factors include mucosal damage from pretransplantation chemotherapy and radiation therapy, steroid therapy, acute GVHD, infectious colitis, small-bowel obstruction, and severe humoral and cellular immunodeficiency.¹¹³ Day and colleagues¹¹³ reported on 18 patients with pneumatosis after bone marrow transplantation. The colon, predominantly the right side, was involved in 17 of 18 cases. Seven of these patients died within 2 weeks after detection of pneumatosis and 1 needed hemicolectomy, whereas the remaining 10 responded well to the conservative treatment. Therefore, in the clinical context of systemic infection or shock, the finding of pneumatosis may be a poor prognostic sign (Fig. 34-111); if it is identified in asymptomatic patients, however, it is probably of little clinical significance.

Diverticular Diseases

Small-bowel diverticula are either congenital or acquired. A congenital diverticulum contains all three intestinal wall layers, usually as a Meckel's diverticulum located on the antimesenteric aspect of the ileum 30 to 60 cm from the ileocecal valve. Acquired diverticula have only mucosal and submucosal layers that herniate through the muscular and serosal layers; they occur at the mesenteric border, in contrast with the true congenital Meckel's diverticulum.

Jejunal diverticula are found twice as frequently in men than in women and occur almost exclusively in persons older than 40 years of age.³⁶⁸ Diverticula tend to be larger and higher in number in the proximal jejunum and smaller

and fewer as one progresses caudally.³⁶⁸ An exception is the terminal ileum, where the diverticula are often multiple.

Acute complications of congenital or acquired diverticula include diverticulitis, with or without abscess or perforation, massive GI hemorrhage, and intestinal obstruction.¹¹⁵ Chronic symptomatology includes chronic abdominal pain, malabsorption, functional pseudo-obstruction, and chronic low-grade GI hemorrhage. Various types of neoplasm can occur in Meckel's diverticulum owing to the presence of heterotopic tissues.⁶¹¹

Small diverticula may not be recognized on CT scans because distinguishing between diverticula and bowel loops is usually impossible. CT findings that may be useful in identifying small-bowel diverticula include (1) large size of the diverticulum (>3 cm), (2) different contents of the diverticulum and adjacent small-bowel loops, and (3) absence of valvulae conniventes.⁹²

Intestinal obstruction may occur as a result of pressure on the intestinal wall from distended diverticula, an inflammatory mass associated with diverticulitis, stricture or adhesions from recent or past diverticulitis, intussusception at the site of the diverticulum, enteroliths developed within the diverticula, or volvulus of the diverticula-containing segment.^{33, 92} On CT scans, the presence of diverticulitis may mimic many other conditions, such as abdominal abscess associated with appendicitis or inflammatory bowel disease, perforated colon cancer, and perforated right-sided colonic diverticulitis. However, diverticulitis can be suggested when an inflammatory mass containing air or oral contrast material with edema of the adjacent mesentery is detected in an unusual location, distant from the area of the ileocecal valve, and from the sigmoid colon (Fig. 34-112); contrast material within a diverticulum may remain for several days after the CT scanning has been completed.

Endometriosis

Endometriosis is a common disease characterized by the presence of ectopic endometrial tissue in an extramyometrial site. About 10% to 15% of women in their reproductive years are affected.

Figure 34-112. Jejunal diverticulitis. CT scan shows diverticular abscess (D) and diffuse perienteric haziness and infiltrates (arrows). (Courtesy of K. C. Cho, Newark, New Jersey.)

Figure 34-113. Small-bowel obstruction caused by endometrial implantation on the ileal loop. The small-bowel loop is dilated (asterisks) with mild bowel wall thickening (arrows). Diffuse granular infiltrates are noted in the perienteric fat plane.

The most commonly accepted theory of pathogenesis is transtubal reflux with peritoneal implantation.¹⁴¹ Alternatively, extrauterine growth of endometriotic tissue can occur as a result of metaplastic transformation of pluripotential peritoneal mesothelium.¹⁴¹ GI tract lesions have been found in about 12% of patients with endometriosis, and 85% of these lesions involved the rectosigmoid, 7% the small bowel, 3% the cecum, and 3% the appendix.³⁶² Ileal endometriosis most often involves the terminal ileum within 10 cm of the ileocecal valve.⁴⁰¹ Endometriotic implants can also affect the proximal ileum or even the jejunum as far proximally as 30 cm from the duodenojejunal junction.

Small-bowel endometriosis may present as cyclic episodes of abdominal pain coinciding with the menstrual cycle, nausea and vomiting, diarrhea, or constipation; however, classic symptoms are seen in only 18% to 40% of patients.⁴¹⁰ Occasionally, this disease may result in acute, chronic, or intermittent small-bowel obstruction by kinking, stenosis, volvulus, or intussusception (Fig. 34-113).²¹⁷

The common radiographic findings include extrinsic mass effect with variable spiculation and tethering of folds.⁴²⁷ Endometrial implants may also present as short annular or plaque-like lesions.⁴²⁷ Muscular hypertrophy and fibrotic reaction may be responsible for the narrowing, tethering, or spiculation of the ileum on barium studies.⁴²⁷ Although colonic involvement commonly coexists, ileal endometriosis can occur in the absence of colonic disease.

Hernias

Abdominal hernias remain a common problem for both clinicians and radiologists. The main types of abdominal hernias are:

- External, or abdominal wall, hernias
- Internal hernias
- Diaphragmatic hernias

In the past, the diagnosis of a hernia was made clinically either with plain radiographs or with barium studies. Currently, specific diagnoses are confirmed more frequently

by CT, especially in patients with nonspecific abdominal complaints. In addition to revealing the anatomic location and type of hernia, CT may provide information regarding the contents and complications of the hernia.

External Hernias

Abdominal wall hernias account for most external hernias and include inguinal, femoral, umbilical, spigelian, and incisional types; rare forms include lumbar and obturator hernias. All abdominal wall hernias consist of a peritoneal sac that protrudes through a weakness or defect in the muscular layers of the abdomen. Abdominal contents may include properitoneal fat, greater omentum, and viscera. Weakness in the transversalis fascia is the main source of predilection for abdominal wall hernia, especially in the groin. Trauma is a rare cause of these hernias.

Inguinal Hernias

Inguinal hernias are either *indirect* or *direct*, depending on their relationship to the inferior epigastric vessels.

In patients with an indirect hernia, the peritoneal sac passes down the course of the inguinal canal anterior to the spermatic cord and lateral to the inferior epigastric vessels. In women, the hernia sac follows the course of the round ligament into the labium. The sac usually contains omentum and small bowel and, occasionally, ascites.

A direct hernia is almost always acquired rather than congenital. The neck of the hernia is medial to the inferior epigastric vessels and generally does not traverse the inguinal canal. Therefore, bowel strangulation is seldom a complication because of the blunt and diffuse character of the protrusion. CT and MRI define the relationship of the inferior epigastric vessels to the hernia sac.

Femoral Hernias

Femoral hernias are far less common than inguinal hernias. They are seldom seen in children and are more common in women. They occur below the inguinal ligament and lateral to the femoral vessels. Bowel strangulation is common.

The diagnosis is easily made by CT. A femoral hernia may be distinguished from an inguinal hernia on CT because its sac lies below and lateral to the pubic tubercle as it emerges from the femoral canal. Conversely, an inguinal hernia lies above and medial to the tubercle.⁵⁹⁶

Incisional Hernias

Incisional hernias are a complication of laparotomy. Most of these hernias develop during the first 4 months after surgery but may remain clinically silent for up to 5 years until their detection.¹³⁶ Vertical incisions are thought to be more likely to result in an incisional hernia than are transverse incisions. Incisional hernias can be seen with incisions as small as a puncture site for laparoscopic surgery.⁵²⁴

A common variation is the *parastomal hernia*, in which bowel and omental fat protrude through a fascial defect immediately adjacent to a colostomy or ileostomy stoma. This type has been reported to occur in as many as 36% of patients with an ileostomy.¹³⁸ If the hernia is left un-

Figure 34–114. Incisional external hernia with intestinal strangulation. CT scan shows marked enhancement of a small-bowel loop (S) herniated in the hernia sac along with a narrowed hernia neck (arrows). Fluid collection is present in the hernia sac.

treated, bowel loops may be incorporated into the hernia and may become incarcerated or strangulated. CT demonstrates the abdominal wall defects and the hernial contents as well as signs of bowel ischemia (Fig. 34–114).

Richter's Hernias

Richter's hernia is an uncommon type of hernia in which only part of the bowel wall becomes involved. Because only a portion of the intestinal wall is incorporated into the hernia, the lumen remains patent and there is no obstruction. Incarceration is uncommon.

Spigelian Hernias

Spigelian hernias occur at a weak point along the lateral border of the rectus muscle at a midpoint between the umbilicus and symphysis pubis. Although rare, they have a high frequency of bowel incarceration and strangulation.

On CT scans, a hernia sac protruding through the linear semilunaris and containing bowel or fat is identified. If it contains only peritoneal fat, it can be mistaken for an abdominal wall lipoma.⁵⁹⁶ However, careful inspection of the images reveals the muscular defect at the linear semilunaris (Figs. 34–115 and 34–116).

Obturator Hernias

Obturator hernias protrude through the obturator foramen alongside the obturator vessels. They occur most often in thin, elderly women. About one third of patients have neuralgia involving the thigh as a result of compression of the obturator nerve in the obturator canal.¹⁰⁵

The diagnosis is made by the presence of herniated bowel protruding through the obturator canal on CT scans or MR images.

Internal Hernias

Internal hernias are the result of herniation of a viscus through a normal or abnormal aperture within the confines of the peritoneal cavity. Hernias that arise when bowel

Figure 34-115. Spigelian hernia. CT scan shows herniation of the mesentery and small-bowel loop into the sac.

herniates through the mesentery or peritoneum do not have a hernia sac. Paraduodenal hernias account for approximately 50% of all internal hernias. Other internal hernias include pericecal, intersigmoid, transmesenteric, and retroanastomotic hernias and herniation through the foramen of Winslow.

Paraduodenal Hernias

Paraduodenal hernias are the most common type of internal hernia. They frequently present with acute intestinal obstruction but may also cause chronic intermittent postprandial abdominal pain. A right paraduodenal hernia results from incomplete rotation of the duodenum during development. They usually contain only small bowel. The anterior wall of the sac comprises transverse colon and mesentery of the ascending colon. The entrance into the hernia sac is most commonly via the mesentericoparietal fossa of Waldeyer, which is in the first part of the jejunal mesentery immediately behind the superior mesenteric ar-

Figure 34-117. Left paraduodenal hernia. The jejunal loops are enveloped by thin capsule of the mesentery (arrows), located at the subperitoneal space.

tery (SMA) and inferior to the third part of the duodenum.^{41, 406}

On CT, right paraduodenal hernias show a retroperitoneal mass, comprising an encapsulated cluster of dilated small-bowel loops, and displacing the right ureter (Fig. 34-117). The SMA and branches of the ileocolic artery are found in the anterior wall of the hernia. Left paraduodenal hernias also involve an anomaly of gut rotation. The bowel becomes entrapped behind the descending mesocolon in a hernia sac created by the fossa of Landzert.

CT may show an abnormal cluster of normal caliber or dilated bowel loops in an abnormal position either behind the body of the pancreas or between stomach and body of pancreas.^{112, 453} The inferior mesenteric vein and ascending left colic artery are located at the anteromedial border of a left paraduodenal hernia.

Herniation through the Foramen of Winslow into the Lesser Sac

Herniation through the foramen of Winslow into the lesser sac may contain small-bowel loops, cecum, ascending and transverse colon, gallbladder, and omentum. CT findings include gas-containing bowel loops within the lesser sac medial and posterior to the stomach (Fig. 34-118). The cecum and ascending colon may be absent from their usual location if they are part of the herniated viscera.

Intussusception

Intussusception is the most common cause of intestinal tract obstruction occurring in young children, but it is relatively uncommon in adults; 5% of all intussusceptions occur in adults, and it accounts for up to 5% of all cases of bowel obstruction in adults.³⁷ In contrast with childhood intussusception, which is idiopathic in 90% of cases, adult intussusception has a demonstrable cause in more than 90% of cases.³⁷ As the intussusceptum enters into the intussusciptum, the mesentery is carried forward and is trapped between the overlapping layers of bowel. Twisting

Figure 34-116. Incarcerated spigelian hernia. CT scan shows bowel thickening, with the “target sign” in the small-bowel loop (S) herniated into the hernia sac, along with diffuse small-bowel dilatation (i) caused by obstruction.

Figure 34-118. Internal (lesser sac) hernia with strangulated small-bowel obstruction. The dilated small-bowel loops (*asterisks*), herniated in the lesser sac, are poorly enhanced because of intestinal strangulation. Diffuse regional mesenteric haziness (M) is also present. (From Ha HK, Kim HS, Lee MS, et al: Differentiation of simple and strangulated small bowel obstructions: Usefulness of known CT criteria. *Radiology* 204:507-512, 1997.)

or severe constriction of the mesenteric vessels may result in vascular compromise with subsequent edematous thickening of the involved bowel. Ischemic necrosis may develop if timely intervention is not undertaken.²⁴⁹

Intussusceptions may be *enteroenteric*, *ileocolic*, or *colocolic* types.

In general, most lead points in the *enteroenteric* intussusceptions are benign, including benign neoplasms, Meckel's diverticula, adhesions, lymphoid hyperplasia and adenitis, trauma, celiac disease, duplications, and inflammatory lesions; small-bowel malignancy (either primary or metastatic) may account for 6% to 30% of cases. Eight percent to 20% of enteroenteric intussusceptions may be idiopathic,⁵⁵⁷ and transient nonobstructing enteric cases associated with physiologic status have also been reported.⁵⁹⁴

Colocolic intussusception is more likely to have a malignant etiology. Postoperative intussusception in adults has been also recognized as a distinct entity and may be related to a variety of predisposing factors, such as suture lines, oversewn ileum in jejunioileal bypass, previous jejunostomy site, adhesions, submucosal bowel edema, intestinal dysmotility, long intestinal tubes, and chronic bowel dilation.⁴ The intussusceptions in patients with AIDS are generally ileum-based and may occur from lymphoma, atypical mycobacterial infection, or other unusual inflammatory process.⁷⁴ Presenting signs and symptoms of intussusception include recurrent intestinal obstruction, intermittent abdominal cramps, and rectal bleeding.

The diagnosis of intussusception is easily made by CT and MRI. The imaging appearance of a bowel-within-bowel configuration with or without contained fat and mesenteric vessels is pathognomonic (Fig. 34-119).⁵⁹⁴ Depending on their orientation to the scanning axis, they may appear either as a round target-shaped mass or as an oblong

Figure 34-119. Ileal lipoma with intussusception. CT scan shows a "bowel-within-bowel" appearance (*arrowheads*). A lipomatous mass (*arrow*) can be seen at the leading point.

sausage-shaped mass. The thick outer rim of soft tissue density represents the edematous wall of the intussusceptum with some contribution from bowel wall of the intussusciptens.

Although CT and MRI are sensitive in detecting the intussusception, morphologic analysis of the lead point may not provide the clue for determining their primary cause in many instances, except for the cases of lipoma. According to a series by Warshauer and Lee,⁵⁹⁴ enteroenteric intussusceptions caused by non-neoplastic lesions were shorter in length, smaller in diameter, and less likely to be associated with obstruction; no neoplastic enteric intussusceptions were shorter than 3.6 cm or smaller than 3.4 cm in diameter.

The determination of the presence or absence of intestinal necrosis in intussusception is important in patient management. On CT, the presence of severe engorgement or twisting (whirl sign) of the mesenteric vessels as well as evidence of loss of layered pattern, extraluminal fluid collection, and bowel perforation may suggest the diagnosis of intestinal necrosis (Fig. 34-120).^{253, 260} The bowel necrosis may be confined to only intussuscepted segment or can extend to longer segment of the bowel.

Small-Bowel Obstruction

Small-bowel obstruction may be caused by several primary causes. According to degree, they may be *complete* or *high-grade partial obstructions* or *low-grade partial obstructions*. The diagnosis is usually made on the basis of clinical signs and patient's history. However, because the clinical symptoms and signs are often nonspecific, radiologic studies (e.g., plain radiograph and barium studies) are considered essential for a diagnosis. Nevertheless, plain radiographic study is diagnostic in only 46% to 80% of cases with common occurrence of false-positive and false-negative interpretations; up to 20% of patients may have no radiographic evidence of obstruction.^{59, 166}

Although barium studies are the standard of reference in diagnosing and characterizing the intestinal obstruction, the results of these studies are sometimes mixed. Further-

Figure 34-120. Intussusception with vascular compromise in a patient who underwent gastrectomy 1 year before. *A*, CT scan shows a heterogeneous mass (arrows) caused by invagination of the mesentery. *B*, CT scan at another level shows diffuse haziness and mesenteric vascular prominence (arrows) along with suspected bowel wall thickening (asterisks) in the loops proximal to the obstruction. At surgery, intestinal strangulation was noted in the small-bowel loops proximal to the intussuscepted site. Bowel adhesion was considered to be the primary cause of intussusception.

more, contrast studies are limited in the evaluation of changes in the peritoneal cavity and abdominal solid organs, may interfere with further diagnostic work-up, such as CT or ultrasonography, and may be misleading, especially when a contrast agent passes into the colon through a high-grade partial obstruction.

CT has been widely used for patients who were thought to have small-bowel obstruction because it is simple to perform and provides information about the site and cause of obstruction, the bowel wall and extraluminal changes, and the presence or absence of intestinal strangulation.

With more experience, however, certain limitations are also identified in this examination.

Because of its multiplanar imaging capability and recent advances in technology, MRI can be used to evaluate small-bowel obstruction, especially in patients whose bowel is filled with residual barium suspension after barium study, who have hypersensitivity to the IV contrast material, or who are pregnant. In most instances, coronal MR images are more useful than axial images in searching for an obstructed site because they produce images comparable to those of small-bowel follow-through (Fig. 34-121). More-

Figure 34-121. Simple intestinal obstruction caused by bowel adhesion. *A*, Coronal half-Fourier acquisition single-shot turbo spin-echo (HASTE) MR image shows diffuse small-intestinal loop dilatation with tapered luminal narrowing at the obstructed site (arrow). *B*, CT scan shows end-on view of a narrowed intestinal segment (arrow) just above the obstructed site.

over, in equivocal cases, more detailed examination of the obstructed site or loops can be made with the help of multiplanar reconstruction or 3D reformatted images (see Fig. 34-98B). Therefore, in such patients it is important to obtain the images without an interslice gap.²¹⁰

For determining the primary causes of small-bowel obstruction, MRI may be equal to or superior to CT. However, both MR and CT appear to have difficulty in determining the primary causes of obstruction when a short segmental stricture is present.

Complete or High-Grade Partial Obstruction

The CT diagnosis of bowel obstruction is based on the detection of a transition zone, dilated fluid or air-filled loops of small bowel proximal to the site of obstruction, and collapsed loops of small bowel or colon distal to the obstructed site. The bowel dilatation is indicated when the luminal diameter exceeds 2.5 cm¹⁷² and should be continuous.¹⁷⁷

Although CT is usually useful for evaluating high-grade obstruction, the transition zone is sometimes difficult to detect. In these circumstances, use of thin-section CT may be helpful not only to determine the level of obstruction but also to reveal their causes. The presence or absence of colonic fluid or gas is also used to distinguish paralytic ileus from small-bowel obstruction. In patients with high-grade small-bowel obstruction, the sensitivity of CT in diagnosis ranges between 81% and 100%.^{166, 367}

Low-Grade Partial Obstruction

The presence of low-grade partial small-bowel obstruction is considered to be present on CT when small-bowel loops are mildly dilated with ill-defined transition zone, incomplete collapse of the distal bowel, and moderate colonic fluid and gas.¹⁶⁶ The diagnosis can be easily misinterpreted as paralytic ileus. Furthermore, because the transition zone is difficult to detect, CT has limitation in determining the level and cause of obstruction. Therefore, small-bowel follow-through or enteroclysis may be necessary for further evaluating patients with suspected low-grade small-bowel obstruction. In contrast to high-grade small-bowel obstruction, the sensitivity of CT in diagnosis of low-grade obstruction is not high (48%).³⁶⁷ The occurrence of intestinal strangulation is rare in these patients.

Simple Small-Bowel Obstruction

Typical cases of simple obstruction may show diffuse bowel loop dilatation with a smooth transition zone or a smooth "beak" at the obstructed site on CT (Fig. 34-122). The bowel wall at the site of obstruction may be minimally thickened or of normal thickness. Mesenteric changes, such as vascular engorgement and haziness, are absent or minimal, and ascites is either absent or minimal (Fig. 34-123). However, the presence of such findings does not always indicate simple obstruction because these changes can also be seen in some patients with strangulated obstruction.

Closed-Loop Obstruction

Most cases of strangulated obstruction are related to closed-loop obstruction. Contrast radiography has no role

Figure 34-122. Simple small-bowel obstruction caused by adhesion and bands. CT scan shows diffuse dilatation of the small intestine with a smooth beak (arrow) at the site of obstruction. (From Ha HK, Rha SE, Kim JH, et al: CT diagnosis of strangulation in patients with small bowel obstruction: Current status and future direction. *Emerg Radiol* 2:47-55, 2000.)

in the acute clinical setting, but its value is in the further work-up of partial obstruction in the subacute or chronic setting when CT cannot answer questions relevant to management.³⁶⁹ The most important CT indicators may include the whirl sign, convergence of mesenteric vessels toward the twisted site, and reversed position of the mesenteric artery and vein (Fig. 34-124)²⁰⁴; the whirl sign, however, is also seen in asymptomatic subjects.

Balthazar and coworkers²⁰ described additional signs of U-shaped or C-shaped configuration of dilated bowel loops and two adjacent collapsed, round, oval, or triangular loops with an "arrowhead" configuration. The *serrated beak sign* (Fig. 34-125), described by Ha and associates,²¹⁴ also indicates the presence of a closed loop associated with regional mesenteric vascular engorgement as well as bowel

Figure 34-123. Simple small-bowel obstruction. CT scan shows diffuse dilatation of small-intestinal loops with ascites. Accumulated fluid collection (arrow) between the mesenteric layers mimics mesenteric haziness. (From Ha HK, Rha SE, Kim JH, et al: CT diagnosis of strangulation in patients with small bowel obstruction: Current status and future direction. *Emerg Radiol* 2: 47-55, 2000.)

Figure 34-124. Closed-loop obstruction due to volvulus. CT scan shows twisting and engorgement of the mesenteric vessels ("whirl sign") (arrows) adjacent to the obstructed site. Note diffuse dilatation of the small intestine (S) and intraperitoneal fluid collection (asterisks). At surgery, strangulation was present in the involved segment. (From Ha HK, Rha SE, Kim JH, et al: CT diagnosis of strangulation in patients with small bowel obstruction: Current status and future direction. *Emerg Radiol* 2: 47-55, 2000.)

wall thickening at the obstructed bowel; this sign also suggests strangulated obstruction.

Strangulated Small-Bowel Obstruction

Strangulation implies interference with the blood supply associated with an obstruction that may not necessarily be complete. In most instances, it occurs as a complication of intussusception, torsion, volvulus, or any other form of closed-loop obstruction. Interference with the blood supply may occur either from twisting of the bowel on the mesentery or from distention of an obstructed closed loop.

Figure 34-125. Strangulated small-bowel obstruction due to adhesions. CT scan shows a serrated beak (arrows) in the bowel loop at the site of obstruction. The bowel wall (arrowheads) in the strangulated segment has lost its definition. A large amount of ascites is present. (From Ha HK: CT in the early detection of strangulation in intestinal obstruction. *Semin Ultrasound CT MRI* 16:141-150, 1995.)

The incidence of strangulation is more than 40% in complete or high-grade obstruction⁵²⁰ but may be less than 10% in low-grade obstruction.⁴⁷ Some researchers¹³⁹ distinguish between long, medium (8 to 20 inches), and short-loop strangulated obstructions as follows:

1. Long strangulated loops tend to cause death by sequestration of large quantities of plasma and blood from circulation.
2. Medium loops tend to cause shock and death by the formation of exotoxins of *Clostridium welchii*.
3. Short loops tend to perforate and cause peritonitis.

With prompt surgical intervention, the strangulating element may be removed before gangrene of the intestine ensues.

The sensitivity of CT in detecting the strangulated obstruction has been reported to range from 83% to 100% in the literature.^{23, 165, 208} The proposed well-known diagnostic CT criteria for strangulated obstruction are as follows:

1. Portal or mesenteric venous gas, pneumatosis intestinalis.
2. Abnormal bowel wall enhancement.
3. Serrated beak sign.
4. Unusual mesenteric vascular course.
5. Diffuse mesenteric vascular engorgement and haziness.
6. Bowel wall thickening.
7. A large amount of ascites.

Although these CT criteria are useful in the diagnosis of intestinal strangulation, most of them, when used alone, are not sufficiently sensitive indicators of simple or strangulated obstruction. Furthermore, some of these findings are also noted in cases of simple intestinal obstruction. Therefore, use of a combination of highly specific findings may increase the diagnostic accuracy of CT in detecting strangulation. In addition, the importance of clinical criteria (abdominal tenderness, tachycardia, fever, and leukocytosis) should not be overlooked. In equivocal cases demonstrated by CT, the presence of none or one of the four clinical criteria had higher chance to have simple obstruction and the patients with three or all to have strangulated obstruction; the presence of two criteria did not help in distinction of strangulated and simple obstruction.

Portal or Mesenteric Venous Gas or Pneumatosis Intestinalis. Of the various findings reported, portal or mesenteric venous gas and pneumatosis intestinalis (Fig. 34-126) are perhaps the most specific signs^{6, 146} and are representative of bowel gangrene. However, the incidence of these signs is very low^{6, 208}; pneumatosis was noted in only one of the 19 patients in one series⁶ and was not found in any of the 41 patients in another series.²⁰⁸ Furthermore, some reports suggest that these findings are not always indicative of intestinal strangulation.^{165, 566}

Abnormal Bowel Wall Enhancement. Absent or poor contrast enhancement in the bowel wall is also an important finding for identifying intestinal strangulation with a sensitivity of 34% and a specificity of 100% (see Figs. 34-125 and 34-126).²⁰⁸ This finding in strangulated segments may be attributable mainly to a perfusion phenomenon, that is, delayed return of the venous blood with

Figure 34-126. Strangulated small-bowel obstruction caused by bands and adhesion. Early phase of the spiral CT scan shows pneumatosis (arrows) and poor contrast enhancement in the strangulated segment of the small-intestinal loops. At the site just proximal to the obstruction, the superior mesenteric artery (arrowheads) is poorly opacified with contrast material as compared with the well-opacified superior mesenteric vein (curved arrow). Diffuse mesenteric haziness (M) is also noted. (From Ha HK, Rha SE, Kim JH, et al: CT diagnosis of strangulation in patients with small bowel obstruction: Current status and future direction. *Emerg Radiol* 2:47-55, 2000.)

subsequent slowing of the arterial supply or arteriospasm. Delayed enhancement may be observed in the strangulated segments in which early-phase spiral CT shows poor contrast enhancement (Fig. 34-127).⁶²¹

The most reliable method of determining whether abnormally enhancing bowel is present is to compare adjacent bowel loops. Because of the importance of analyzing the contrast enhancement pattern, it is better to avoid the use

of oral contrast medium and to use dynamic CT study in patients thought to have small-intestinal obstruction due to adhesions, bands, or hernia.

Serrated Beak Sign. This sign (see Fig. 34-125), described in one series,²¹⁴ is highly specific in the diagnosis of strangulation; however, CT interpretation of this sign is problematic. The configuration of beaklike narrowing changes with different imaging planes, causing low sensitivity of this sign and yielding poor interobserver agreement.²⁰⁸

Unusual Mesenteric Vascular Courses. Most strangulated obstructions are associated with torsion or twisting of both bowel and mesenteric vessels. Therefore, CT findings of an unusual mesenteric vascular course offer an important clue to the presence of closed-loop obstruction with intestinal strangulation. As described earlier, these findings include the whirl sign, converging of the mesenteric vessels toward one point, and reversed position of the mesenteric artery and vein (Fig. 34-128; see also Figs. 34-124 and 34-127). However, caution is needed when one is using CT to interpret these signs because they can be seen in asymptomatic subjects without closed-loop or strangulated obstruction (Fig. 34-129).

Diffuse Mesenteric Vascular Engorgement and Haziness. Although a mild degree of mesenteric changes, such as vascular engorgement and haziness, are seen in simple obstruction,^{208, 214} diffuse or severe mesenteric change is one of the highly sensitive and specific CT signs of intestinal strangulation (see Figs. 34-126 and 34-127).^{20, 208, 165} One should be cautious not to interpret the localized peritoneal fluid accumulated in the spaces between the two mesenteric layers as mesenteric haziness.

Bowel Wall Thickening. The likelihood of strangulated obstruction may increase when the bowel wall be-

Figure 34-127. Strangulated small-bowel obstruction caused by bands and adhesion. A and B, CT scan shows different degrees of contrast enhancement (arrows) in the thickened bowel wall of the same strangulated segment. Diffuse engorgement and haziness (arrowheads) are seen in the vasa recta of the regional mesentery. (From Ha HK, Rha SE, Kim JH, et al: CT diagnosis of strangulation in patients with small bowel obstruction: Current status and future direction. *Emerg Radiol* 2:47-55, 2000.)

Figure 34-128. Closed-loop obstruction caused by volvulus. CT scan shows convergence (arrow) and engorgement of the mesenteric vessels. Small-intestinal loops are poorly enhanced compared with the colonic loops. Intestinal strangulation was confirmed at surgery. (From Ha HK, Kim HS, Lee MS, et al: Differentiation of simple and strangulated small bowel obstructions: Usefulness of known CT criteria. *Radiology* 204:507-512, 1997.)

comes thicker. To assess bowel wall thickness accurately, Maglinte and colleagues³⁶⁷ stressed the importance of not using oral contrast material in patients who showed definite or probable small-intestinal obstruction on abdominal radiography because the presence of hyperattenuated intraluminal fluid made it difficult to determine wall thickening. When strict criteria (5 mm) were used, CT findings of bowel wall thickening showed high specificity (88%) with a sensitivity of 54% in distinguishing the simple from strangulated obstruction.²⁰⁸ However, the bowel wall is thinned out or occasionally invisible when the bowel becomes gangrenous (see Fig. 34-122).

The thickened bowel wall may sometimes show the target sign (Fig. 34-130) due to submucosal edema or hemorrhage.

Figure 34-129. Subtotal gastrectomy with gastrojejunostomy performed for gastric cancer in an asymptomatic patient. The CT scan, obtained for routine follow-up study, shows twisting of the mesenteric vessels ("whirl sign") (arrows). (From Ha HK, Rha SE, Kim JH, et al: CT diagnosis of strangulation in patients with small bowel obstruction: Current status and future direction. *Emerg Radiol* 2:47-55, 2000.)

Ascites. In strangulated obstruction, there is rapid blood and plasma loss into the involved small-bowel loops or peritoneal cavity. It is therefore not surprising that the presence of a large amount of ascites is an indicator of strangulation (see Fig. 34-130).²⁰⁸ However, the presence of a large amount of ascites in patients with small-bowel obstruction is not always related to the obstruction and can be caused by many other conditions. Therefore, before this finding is used as a specific indicator in the diagnosis of strangulation, it is necessary to exclude other diseases as necessary. If results are questionable, paracentesis should be performed because peritoneal fluid is reddish brown

Figure 34-130. Strangulated small-bowel obstruction in an afferent loop in a 43-year-old man after subtotal gastrectomy with gastrojejunostomy for gastric cancer. CT scan shows bowel wall thickening of the afferent loop (A) with the "target sign." A large amount of ascites is present in the peritoneal cavity. (From Ha HK, Rha SE, Kim JH, et al: CT diagnosis of strangulation in patients with small-bowel obstruction: Current status and future direction. *Emerg Radiol* 2:47-55, 2000.)

or yields *Escherichia coli* with culture in patients with strangulated obstruction.³²⁷

Primary Causes of Obstruction

Small-bowel obstruction may be caused by three types of abnormalities:

1. Obturation of the intestinal lumen (polypoid tumor, gallstone, bezoars).
2. Intrinsic bowel lesions (congenital atresia or stenosis, adenocarcinoma).
3. Lesions extrinsic to the bowel (adhesions, hernia, peritoneal carcinomatosis).

Among these lesions, the most common cause is adhesions, followed by malignancy and hernia.⁴⁷ CT may determine the cause of obstruction in 73% to 85% of the cases.^{166, 396}

Adhesions

In general, adhesions and bands themselves are not visible on CT because they are thin, fibrous connective tissues. However, indirect findings may help in their detection, which include close attachment of collapsed loops along the abdominal incisional wound, abrupt cut-off of the bowel in a linear orientation, and unusual clustering of the bowel loops.²⁰⁴ The obstructed site caused by an adhesion or a band may appear as a beaklike luminal narrowing on CT. Inability to visualize an obstructive lesion, such as a tumor, intussusception, or abscess, may be diagnostic of obstruction caused by adhesions.¹⁸

Hernias

A variety of external and internal abdominal hernias can cause bowel obstruction. Although CT is excellent for detecting and characterizing types of hernias and for demonstrating the bowel, mesentery, or omentum within a hernia sac, it is especially valuable in patients who have symptoms of small-bowel obstruction, possibly resulting from hernia, but who have no hernia apparent on physical examination.

Incarceration usually occurs as a result of a narrow hernia ring, which leads to bowel obstruction and may cause strangulation of the hernia sac and its contents (see Fig. 34-114). Small-bowel obstruction caused by internal hernia can be predicted when CT shows abnormal location of bowel loops, crowding of small-bowel loops, and an unusual course of mesenteric vessels (see Fig. 34-118). Because the hernia may not be recognizable if it is reduced spontaneously, it is better to perform CT during symptomatic periods. Defects in the small-bowel mesentery, usually through a small hernia ring, may show a high frequency of strangulation and intestinal gangrene.

Bezoars

A phytobezoar is a concretion of poorly digested fibers, fruit seeds, and pulpy fruits, especially oranges and persimmons, causing small-intestinal obstruction usually after migration of a gastric phytobezoar. However, the obstruction is also caused by a primary bezoar (an enterolith) formed in the small intestine in association with underlying small-

Figure 34-131. Intestinal obstruction caused by phytobezoar. CT scan shows an ovoid mass (arrows) containing mottled gas at the ileum along with diffuse small intestinal dilatation due to obstruction.

bowel diseases such as diverticula, strictures, or tumors.¹⁸⁹ Gastric surgery is the most predisposing factor for the development of phytobezoar; other factors include poor mastication, autonomic neuropathy, and overindulgence of foods with a high fiber content.²³¹ Early diagnosis is important because phytobezoars provoke decubitus ulcer, pressure necrosis, perforation, and even strangulation if the diagnosis is delayed.²³¹

The most common CT findings of phytobezoars include a round or ovoid or a long sausage-shaped mass containing mottled gas at the obstructed site (Fig. 34-131).³⁰⁵ Phytobezoars are rarely manifested as a soft tissue mass without gas, resembling an intraluminal tumor or intussusception. In these cases, barium study may give the clue in suggesting the diagnosis, and the diagnosis should be suspected when intraluminal filling defects appear to be mobile or multiple.

Some bezoars (enteroliths) appear as a calcified intraluminal mass with a laminated appearance.²³¹ In the differential diagnosis, small-bowel feces, which develop proximal to the obstructed site in patients with high-grade small-bowel obstruction, mimic those signs of phytobezoars on CT. With MRI, phytobezoars appear as a hypointense mass on T1-weighted and T2-weighted MR images, and the hypointensity may be due to their high fiber content and admixture of internal gas.

Gallstone Ileus

Gallstone ileus refers to erosion of a gallstone into the GI tract with subsequent development of bowel obstruction. This condition occurs in 0.3% to 0.5% of all cases of cholelithiasis.¹¹⁴ Although the duodenum is the most common site, cholecystenteric fistula can occur in the colon or stomach.¹¹⁴ Stones larger than 2.5 cm may cause obstruction. Bowel obstruction can occur preferentially at the narrow portion of the GI tract, such as the duodenum, the ligament of Treitz, the terminal ileum, or any area of stricture.

CT findings include gas in the gallbladder or biliary tree, calcified gallstone in the dilated bowel, and intestinal obstruction (Fig. 34-132).²⁰¹ The duodenal wall may appear

Figure 34-132. Gallstone ileus. *A*, CT scan shows a high-attenuated stone (arrowheads) obstructing the small-bowel loop. *B*, CT scan at higher level shows contracted and gas-filled gallbladder (arrow) with diffuse pericholecystic infiltration.

thickened with inflammatory infiltration in the pericholecystic space and focal or diffuse loss of interface between the gallbladder and duodenum.

Bowel Obstruction after Abdominal Surgery for Malignancy

Bowel obstruction in patients who have undergone abdominal surgery for malignancy remains a vexing problem in which the cause of obstruction may be benign postoperative adhesions, a focal malignant deposit, or peritoneal carcinomatosis. Approximately 25% of these cases are due to benign causes, a resectable or easily bypassed local recurrence, or a potentially curable new primary tumor.^{286, 443} For this reason, patients with cancer who do not have proven recurrent tumor or peritoneal carcinomatosis should undergo aggressive treatment with early surgery in response to failure of conservative management.⁶⁸ Benign obstruction is more likely if pelvic irradiation was used in the management of the primary tumor, whereas the chance of malignant obstruction is increased if the patient had known metastatic cancer or if the primary cancer is in an advanced stage or of gynecologic origin.^{286, 443}

When one is predicting the causes of intestinal obstruction, it is helpful to consider the time interval from the cancer surgery to the development of intestinal obstruction. The common causes of bowel obstruction during the early postoperative period (<3 months after surgery) are adhesions and bands, volvulus, or other benign conditions, such as stricture due to postsurgical fibrosis.^{215, 552} The site of intestinal obstruction is also another useful indicator in differentiating malignant from benign obstruction. The presence of colonic obstruction favors the diagnosis of malignant obstruction.

According to a series by Megibow and coworkers,³⁹⁶ CT was successful in determining the cause of obstruction in 12 of 13 patients. A later report by Ha and associates²¹⁵ showed that the diagnostic accuracy of CT in differentiating benign from malignant obstruction was 84%. The most diagnostic and specific CT findings to suggest malignant obstruction are the mass at the obstructed or prior surgical site and diffuse omental infiltration or cake (Fig. 34-133); however, if intestinal obstruction develops with implanted

lesions smaller than 5 mm, they can be mistaken for a benign obstruction.

The lymphadenopathy in the para-aortic space or along the upper major vessels of the aorta favors the diagnosis of malignant obstruction, whereas the presence of hematogenous metastases to the other organs (e.g., liver, lung, or bone) may not.²¹⁵ In some instances, observation of bowel loop configuration at the site of obstruction on CT is also valuable. The transition zone at the site of obstruction is commonly abrupt in malignant obstruction and smooth in benign obstruction, whereas bowel wall thickening at obstructed sites is commonly irregular in malignant obstruction and smooth in benign obstruction. A large amount of ascites can be seen in both conditions.

Mesenteric Ischemia

Mesenteric ischemia is a devastating disease process that frequently poses a challenge to clinicians. This disease

Figure 34-133. Malignant small-bowel obstruction due to peritoneal tumor seeding after surgery for gastric cancer. CT scan shows irregular mass (M) obstructing the small-bowel loop. (From Ha HK, Shin BS, Lee SI, et al: Usefulness of CT in patients with intestinal obstruction who have undergone abdominal surgery for malignancy. *AJR Am J Roentgenol* 171:1587-1593, 1998.)

can be classified as *acute* or *chronic* and has a *venous* or *arterial* origin. Bowel viability is not compromised in the chronic form because collateral blood flow will occur. In the acute form, infarction of bowel is more common. Ischemia of arterial origin occurs much more often than venous disease.⁵⁶

The conditions most frequently leading to mesenteric ischemia include vascular occlusion due to arterial or venous disease and hypoperfusion associated with nonocclusive vascular disease. Many other diseases may also cause

such vascular changes, including bowel obstruction, neoplasm, vasculitis, inflammatory conditions, trauma, and iatrogenic causes such as drug or radiation therapy. Irrespective of the cause of the ischemic insult, the end results are similar and range from transient alteration of bowel activity to transmural hemorrhagic necrosis.

CT has been used as a diagnostic tool in patients with suspected mesenteric ischemia. CT helps in detecting changes in the vessels and the bowel and reveals other ancillary abdominal findings. Furthermore, the use of dy-

Figure 34-134. Intestinal ischemia due to multiple arterial emboli. CT scan (A) shows a hypoattenuated occlusive lesion (arrowhead) in the root of the superior mesenteric artery, which is well demonstrated on axial T2-weighted (true fast imaging with steady-state precession [FISP]) (B) and gadolinium-enhanced (C) MR images. CT scan (D) at a lower level shows a small embolus in the branch of the superior mesenteric artery; however, the embolus is difficult to see on true-FISP (E) and contrast-enhanced (F) MR images.

dynamic CT provides information regarding the hemodynamics of blood flow to the intestine. Specific CT signs for establishing the diagnosis include thromboembolism in the mesenteric vessel, intramural gas, portal venous gas, lack of bowel wall enhancement, and ischemia of other organs; nonspecific signs are bowel dilatation, bowel wall thickening, bowel obstruction, mesenteric edema and vascular engorgement, and ascites.^{6, 302, 549, 566}

MRI has been attempted in cases of suspected mesenteric ischemia. Unenhanced MR images are comparable with CT for demonstrating changes in the bowel and adjacent mesentery, but a significant problem is posed in regard to detecting small thromboemboli in the peripheral mesenteric arterial branches (Fig. 34–134).²¹⁰ As in CT, use of a contrast infusion study may be mandatory not only to assess the dynamic changes in the bowel wall but also to detect small thromboemboli. In addition, some researchers have attempted to use the cine phase-contrast MRI to quantitate mesenteric vascular blood flow.³⁴⁹ In the study by Li and colleagues,³⁴⁹ the percentage change in SMA blood flow 30 minutes after meal intake seems to be a promising criterion for differentiating healthy subjects from patients with chronic mesenteric ischemia. However, further study with a large number of patients is warranted.

Thromboembolism

Occlusive intestinal ischemia is usually caused either by arterial or venous disease, although arterial occlusion accounts for most cases.⁵⁶ More than 95% of patients with embolic occlusion of the SMA have documented histories of cardiac disease, with the emboli usually originating from a left atrial or ventricular mural thrombus. The embolus lodges at points of normal anatomic narrowing immediately distal to the origin of a major arterial branch. Most patients with SMA thrombosis also have a history of coronary, cerebrovascular, or peripheral arterial insufficiency, and thrombosis occurs at points of severe atherosclerotic narrowing, most often at the origin of the SMA.⁵⁶

Before symptoms are expected, the degree of arterial narrowing must be severe, with narrowing of the cross-sectional area by 50% to 80%.¹²³ In addition to the arterial luminal narrowing, systemic blood pressure and the degree of collateral circulation also play a role in determining the severity of a patient's symptoms and the extent of ischemic insult.³¹ If collateral circulation is adequate, bowel infarction may not develop even in cases with total occlusion of the main SMA or inferior mesenteric artery.

Although angiography remains the most valuable method of diagnosis and the immediate therapy of acute arterial occlusion, CT has recently been regarded as a valuable tool in a noninvasive diagnostic method. In the radiologic literature, reports of sensitivity of CT in diagnosis of acute mesenteric ischemia have varied. In an early report,⁵⁴⁹ the sensitivity of CT was poor (only 39%); more recent series using high-quality infusion techniques^{302, 566} have shown much higher sensitivity (ranges, 64% to 82%). Such improved diagnostic accuracy results mainly from higher detection rates of specific signs of mesenteric ischemia, such as thromboembolism in the mesenteric vessels and lack of bowel wall enhancement (Fig. 34–135). If good contrast enhancement is achieved in the mesenteric vessels,

Figure 34–135. Bowel infarct caused by mesenteric arterial embolic occlusion with iodinated poppyseed oil (Lipiodol) after hepatic arterial embolization for hepatocellular carcinoma. CT scan shows concentric bowel wall thickening of the ileum with intestinal pneumatosis (arrows). The wall of the ascending colon is also thickened (arrowheads). A hyperattenuated Lipiodol (curved arrow) occludes the ileocolic branch of the superior mesenteric artery. (From Rha SE, Ha HK, Lee SH, et al: CT and MR imaging findings of bowel ischemia according to the various primary causes. *Radiographics* 20:29–42, 2000.)

most of thromboemboli in the superior mesenteric vein and large branches of the SMA are easily detected on CT (Fig. 34–136; see also Fig. 34–134). However, it is likely that significant limitation is encountered in detecting small thromboemboli in the peripheral arterial branches. In fact, angiography appears to be not much better than CT in cases of thromboembolism in the peripheral or terminal mesenteric branches.

In one series,⁵⁶⁶ only nonspecific CT findings of mesenteric ischemia, such as diffuse bowel dilatation, bowel wall thickening, ascites, and mesenteric haziness and vascular engorgement, were observed in 36% of the patients with proven mesenteric ischemia (Fig. 34–137). Furthermore, in many instances, it is difficult to obtain high-quality images because of the generally poor condition of patients with mesenteric ischemia; thus, specific CT findings can be easily missed. In such patients with nonspecific CT signs, it is difficult to differentiate mesenteric ischemia from other GI tract disease (e.g., inflammatory bowel disease, acute abdominal conditions). A high index of suspicion may be the key for early identification of acute mesenteric ischemia, especially in patients older than 50 years of age who have chronic heart disease and long-standing congestive heart failure and who show atheromatous vascular wall calcifications on CT studies.

Nonocclusive Mesenteric Ischemia

In patients with nonocclusive mesenteric ischemia, the mesenteric arteries and veins are patent but flow through them is too slow to deliver enough oxygenated blood to the bowel. This condition is most commonly related to primary cardiac dysfunction, such as cardiac failure, arrhythmia, myocardial infarction, sepsis, trauma, and vascular insufficiency. Most cases of colonic ischemia belong to this group. Flow to the viscera is reduced by progressive

Figure 34-136. Intestinal ischemia resulting from mesenteric venous thrombosis. *A*, CT scan shows thrombus (arrow) in the superior mesenteric vein. Note diffuse bowel wall thickening (asterisks) of the small-bowel loop with poor contrast enhancement. *B*, Thick-slab (20-mm), coronal maximum intensity projection image shows favorable demonstration of the poorly enhancing ischemic intestinal segment (asterisks) as well as prominence of the regional vasa recta of the mesenteric vessels.

Figure 34-137. Intestinal ischemia due to mesenteric arterial occlusion. *A*, CT scan shows nonspecific bowel wall thickening (arrows) of the ileum with prominent mesenteric vessels in the regional mesentery. Thromboembolism is not definitively demonstrated. *B*, Arterial phase of the superior mesenteric artery (SMA) angiogram shows occlusion (arrow) of the ileocolic branch of the SMA. *C*, Venous phase of the SMA angiogram shows delayed pooling (arrows) of contrast material in the ischemic ileal segment. (From Ha HK: CT in the early detection of strangulation in intestinal obstruction. *Semin Ultrasound CT MRI* 16:141-150, 1995.)

Figure 34–138. Shock bowel in a 26-year-old woman after cesarean section. CT scan shows diffuse bowel wall thickening in the ileum (arrows) with a large intraperitoneal fluid collection caused by hemoperitoneum. (From Rha SE, Ha HK, Lee SH, et al: CT and MR imaging findings of bowel ischemia according to the various primary causes. *Radiographics* 20:29–42, 2000.)

vasoconstriction, and persistent vasoconstriction of the splanchnic vasculature results in intestinal hypoxia.⁵⁶

Shock bowel, caused by prolonged hypoperfusion due to hypovolemic shock, is a subtype of nonocclusive mesenteric ischemia. It is a transient phenomenon and resolves with restoration of hypovolemia. CT scans may show diffuse bowel wall thickening and contrast enhancement exclusively in the small intestine (Fig. 34–138).⁴¹² Other reported CT manifestations include diminished caliber and increased enhancement of the inferior vena cava and aorta as well as intense contrast enhancement of the kidneys and mesentery.⁵⁴⁷

Shock bowel should be distinguished from diffuse edema of the small bowel that accompanies central venous hypertension due to aggressive volume resuscitation in a trauma setting. Such cases demonstrate other signs of elevated central venous pressure, including an enlarged inferior vena cava, periportal lymphedema, and accumulation of retroperitoneal fluid⁵³⁶ and do not exhibit increased contrast enhancement of the small-bowel wall.

Vasculitis

Vasculitis can affect blood vessels of all sizes, resulting in necrosis and inflammation. The extent and clinical course depend on the size and location of the vessels involved.⁵²⁹ In the 1990s, the predominant type of affected vessel was generally accepted as the criterion for classification.²⁶⁸ According to this system, vasculitis can be classified into three types:

1. *Large-vessel* vasculitis includes Takayasu's arteritis and giant cell arteritis.
2. *Medium-sized vessel* vasculitis includes polyarteritis nodosa (see later) and Kawasaki's disease.
3. *Small-vessel* vasculitis comprises microscopic polyangi-

itis (hypersensitivity vasculitis), Wegener's granulomatosis, Churg-Strauss syndrome, Henoch-Schönlein syndrome, SLE, rheumatoid vasculitis, and Behçet's disease.

Systemic vasculitis affecting the GI tract is uncommon. The frequency of GI involvement depends on the type of vasculitis, with the highest incidence (50% to 70%) in cases of polyarteritis nodosa. With larger-vessel involvement, abdominal manifestations may be indistinguishable from those of mesenteric ischemia caused by emboli or thrombosis except for associated evidence of systemic disease.

Inflammation of medium-sized arteries may also lead to the formation of aneurysms, as commonly occurs in polyarteritis nodosa, and their rupture may cause GI or intra-abdominal hemorrhage. The vasa recta and intramural arteries and arterioles may be affected in virtually all disorders associated with systemic vasculitis. Ulceration and stricture formation are common, but perforation is less common with small-vessel involvement.

Until recently, the medical literature has not sufficiently dealt with the role of radiology in distinguishing ischemia caused by mesenteric vasculitides from that attributed to other causes. If only radiologic findings are used, it may be quite difficult to determine the primary causes of GI manifestations. Knowledge of the systemic clinical manifestations in patients with mesenteric ischemia not only would suggest the possibility of vasculitis but also would be helpful in establishing the specific diagnosis.

In our experience, CT helps to suggest the diagnosis of vasculitis. The possibility of vasculitis should be considered when:

1. Multiple abdominal organs are involved.
2. Mesenteric ischemic changes are suspected in young patients.
3. Involvement of the stomach, duodenum, or rectum coexists with small-bowel and large-bowel changes.
4. The bowel wall changes concomitantly involve both the small and large intestine.²⁶⁸

Ancillary findings occurring in other organs may also suggest the diagnosis because a high incidence of genitourinary tract involvement (nephritis, cystitis, or hydronephrosis) or splenomegaly has also been reported.⁷⁰

Polyarteritis Nodosa

Polyarteritis nodosa is a fibrinoid necrotizing vasculitis that mainly involves the medium-sized muscular arteries. A characteristic finding is multiple aneurysm formation in these vessels, which are seen in 50% to 60% of the cases; the individual lesions affect the branch points and bifurcation of arteries.

The kidney is most commonly involved (80% to 90%), followed by the GI tract (50% to 70%), the liver (50% to 60%), the spleen (45%), and the pancreas (25% to 35%).^{430, 583} Of the GI tract, the small intestine is most commonly affected, followed by the mesentery and colon.

Approximately two thirds of patients with polyarteritis nodosa have abdominal pain, nausea, vomiting, or other GI symptoms in association with organ damage due to ischemia and infarction; GI hemorrhage occurs in roughly 6%

Figure 34-139. Polyarteritis nodosa. A, CT scan shows bowel wall thickening of the ileum and ascending and descending colon (arrows) with evidence of the “target sign.” Also noted are a large amount of ascites and bilateral ureteral dilatation (arrowheads). B, CT scan shows rectal wall thickening (arrows) with the target sign. The bladder (B) is also diffusely thickened. (From Ha HK, Lee SH, Rha SE, et al: Radiologic features of vasculitis involving the gastrointestinal tract. *Radiographics* 20:779–794, 2000.)

of cases, bowel perforation in 5%, and bowel infarction in 1.4%.^{71, 430} Therapy with corticosteroids and cyclophosphamide results in remission or cures in 90% of affected patients.⁵²⁹

The diagnosis can be suggested by the presence of aneurysms up to 1 cm in size within the renal, mesenteric, and hepatic vasculature on angiography; however, these visceral aneurysms are not always a pathognomonic finding because they are also seen in necrotizing angiitis associated with drug abuse²²⁰ and other vasculitides, such as Wegener's granulomatosis and SLE.⁵⁸³ Without angiography, the correct diagnosis is established by biopsy of subcutaneous nodules or skeletal muscle.³⁶⁴

CT may help in determining the extent of involvement in multiple abdominal organs. When the GI tract is involved, CT manifestations do not differ from intestinal ischemia resulting from other causes (Fig. 34-139).²⁶⁷

Microscopic Polyangiitis

Microscopic polyangiitis is characterized by pauci-immune necrotizing small-vessel vasculitis without clinical or pathologic evidence of necrotizing granulomatous inflammation.²⁶⁸ The lesions are thought to represent a hypersensitivity reaction to drugs (e.g., penicillin), microorganisms, heterologous proteins, and tumor antigens,⁵²⁹ and they involve the skin, mucous membranes, lung, brain, heart, GI tract, kidneys, and muscle. In many instances, the lesions are limited to the skin (cutaneous leukocytoclastic vasculitis). The radiologic findings, when the GI tract is involved, do not differ from findings of other types of vasculitis involving similar-sized vessels, and bowel infarction or perforation is rarely reported (Fig. 34-140).²⁹³ In contrast to the findings of polyarteritis nodosa, visceral angiographic results are usually normal and do not reveal microaneurysms.

Henoch-Schönlein Syndrome

Henoch-Schönlein syndrome is one of the subgroups of hypersensitivity-related acute small-vessel vasculitis.⁴⁰⁷

Although the cause is unknown, immunization, insect bites, medications, infections, and certain foods sometimes play a role in the development of this disease. The syndrome occurs most commonly in children between 3 and 10 years of age, but in some series, 30% of affected patients have been older than age 20 years.

The diagnosis is based on characteristic clinical signs and symptoms, such as skin rash, arthritis involving the large joints, colicky abdominal pain, GI bleeding, and hematuria.⁴⁰⁷ The GI manifestations are thought to be related to edema and intramural hemorrhage. When GI symptoms predominate or precede skin lesions, the syndrome may mimic a number of acute abdominal diseases, resulting in unnecessary laparotomies. GI hemorrhage is confined mostly to the mucosa and submucosa, and full-thickness

Figure 34-140. Microscopic polyangiitis (hypersensitivity vasculitis). CT scan shows bowel wall thickening of the ileum (asterisks) with the “target sign.” A small amount of ascites is also visible. (From Ha HK, Lee SH, Rha SE, et al: Radiologic features of vasculitis involving the gastrointestinal tract. *Radiographics* 20:779–794, 2000.)

Figure 34-141. Henoch-Schönlein purpura with bowel infarct in a 6-year-old boy with symptoms of severe colicky abdominal pain, vomiting, and polyarthralgia. The patient had purpura on both buttocks on physical examination. The diagnosis was made on the basis of histopathologic results following surgery (segmental ileal resection). *A*, CT scan shows bowel wall thickening (asterisks) of the ileum with the "target sign." Ascites is also noted. *B*, Small-bowel follow-through shows luminal narrowing and circular fold thickening in both the jejunum (arrows) and the ileum (arrowheads) with skipped areas. (From Ha HK, Lee SH, Rha SE, et al: Radiologic features of vasculitis involving the gastrointestinal tract. *Radiographics* 20:779-794, 2000.)

necrosis and perforation of bowel loop are rare. Therefore, most GI manifestations are self-limited without residua, and only 3% to 5% of cases develop bowel infarction, perforation, or irreducible intussusception.³⁷⁸

No specific findings are seen on radiologic examinations, although the CT finding of multifocal bowel wall thickening with skipped areas under the clinical backgrounds is important to establish a diagnosis (Fig. 34-141).²⁶⁹

Systemic Lupus Erythematosus

SLE is an autoimmune disorder, affecting the musculoskeletal system, kidneys, GI tract, or skin.⁵⁶⁴ Local deposition of antigen-antibody complexes or antibodies inducing necrotizing vasculitis is the presumptive cause of this disease. Most patients range between 16 and 41 years of age, with the most common occurrence during childbearing ages.

A diagnosis of SLE can be made with 98% specificity and 97% sensitivity if at least 4 of 11 diagnostic criteria are present at any time during the course of disease⁵⁶⁴; these criteria include malar rash; discoid rash; photosensitivity; oral ulcers; arthritis; serositis; antinuclear antibodies; and renal, neurologic, hematologic, and immunologic disorder.

SLE may involve any part of the GI tract from the esophagus to the colon, but the territory of the SMA is more preferentially affected. Other sites, such as the stomach, duodenum, colon, or rectum, may also be involved. Inflammation of the small blood vessels of the gut produces a spectrum of complications, including intestinal ischemia, hemorrhage, ileus, ulceration, infarction, and perforation.³⁰¹

CT facilitates more accurate diagnosis of mesenteric arteritis. Common CT findings include dilated bowel, focal or diffuse bowel wall thickening, engorged mesenteric ves-

sels with a comblike arrangement (comb sign), ascites, and lymphadenopathy (Figs. 34-142 and 34-143).⁷⁰ In most cases, the segments of bowel wall thickening are multifocal and are not confined to a single vascular territory because mesenteric vasculitis may affect several vessels simultaneously.³⁰⁰ Rather than bowel wall changes, the ancillary findings occurring in other organs may suggest the diagnosis because a high incidence of genitourinary tract involvement (lupus nephritis, cystitis, or hydronephrosis) has been reported.³ Hydronephrosis also occurs in other types of vasculitis (e.g., polyarteritis nodosa, Henoch-Schönlein syndrome) and seems to be caused either by detrusor muscle spasm with subsequent vesicoureteral reflux or by fibrosis of the ureterovesical junction.^{63, 291}

Behçet's Syndrome

Behçet's syndrome is a well-recognized nonspecific necrotizing vasculitis that affects many organs; its well-known clinical manifestations include orogenital ulceration, uveitis, arthritis, and neurologic and GI involvement.^{256, 381} Among patients with Behçet's syndrome, the GI tract has been reported to be involved in 10% to 40% of the cases⁴⁴²; the usual site is the ileocecal area, especially the terminal ileum.

The hallmark of the syndrome is the presence of large, deeply penetrating ulcerations of the submucosa, the muscle layer, or the entire intestinal wall. As a result, a high incidence of complications, such as perforation, hemorrhage, fistula, and peritonitis, has been reported.²⁷⁷ An appropriate treatment, therefore, is of great importance in avoiding these complications.

Barium study shows a large ovoid or geographic ulcer with marked thickening of the surrounded intestinal wall at the sites of involvement, although in certain instances small, multiple, discrete, and punched-out ulcers can be

Figure 34-142. Systemic lupus erythematosus in a 26-year-old woman. A, CT scan shows bowel wall thickening of the third and fourth portions of the duodenum (*arrows*) with the “target sign.” Splenomegaly and a small amount of ascites are also noted. B, CT scan shows bowel wall thickening of the small intestine with the target sign. C, Mesenteric vascular engorgement (*arrows*) and a large amount of ascites are also noted.

seen. CT has proved effective not only for detecting primary lesions but also for excluding extraluminal complications.²¹² On CT scans, the involved bowel shows concentric bowel wall thickening or a polypoid mass (Figs. 34-144 and 34-145). The polypoid, masslike lesions may reach a diameter of 8 to 10 cm in some cases, with central ulceration in one third of these cases. Most of the thickened

bowel wall may show marked contrast enhancement, presumably owing to vasculitis and perivascularitis.²¹² Other CT findings include minimal lymphadenopathy of less than 1 cm in diameter and fibrofatty proliferation.

In patients with no complications, perienteric or pericolic infiltrations are usually absent or minimal. In contrast, the presence of severe perienteric or pericolic infiltra-

Figure 34-143. Systemic lupus erythematosus. A, CT scan shows edematous gastric wall thickening (*asterisks*). B, The duodenal and ileal walls are also similarly thickened (*arrows*). (From Ha HK, Lee SH, Rha SE, et al: Radiologic features of vasculitis involving the gastrointestinal tract. *Radiographics* 20:779-794, 2000.)

Figure 34-144. Behçet's syndrome. A, Double-contrast barium enema shows multiple, discrete ulcers with thickened mucosal folds (arrows) at the terminal ileum. B, CT scan shows both bowel wall thickening (arrows) and a polypoid masslike lesion (P) at the ileocecal region. (From Ha HK, Lee SH, Rha SE, et al: Radiologic features of vasculitis involving the gastrointestinal tract. *Radiographics* 20:779-794, 2000.)

tions raises the possibility of complications such as micro-perforation and localized peritonitis (Fig. 34-146).

Drug-Induced Enteropathy

A variety of medications can cause injury to any part of the GI tract by different mechanisms. Although GI reactions may be minor in many instances, serious drug-induced complications, such as bowel ischemia, perforation,

peritonitis, or shock, are not uncommon and are sometimes fatal.

Oral contraceptives and estrogens are the well-known drugs causing an increased incidence of thromboembolic complications in the superior and inferior mesenteric arteries, celiac artery, superior and inferior mesenteric veins, and hepatic vein.¹⁶³ The duration of drug therapy with these agents before development of ischemic bowel disease ranges from 10 days to 11 years.¹⁶³ Many instances of oral contraceptive, steroid-induced mesenteric ischemia have mimicked Crohn's disease but are reversible on discontinuation of the agent.⁵⁶⁹

Digoxin and certain cardiovascular agents³⁴⁷ can also

Figure 34-145. Recurrent Behçet's syndrome at the surgical anastomosis. CT scan shows concentric bowel wall thickening (asterisks) at the anastomotic site after right hemicolectomy. Perienteric infiltration and regional mesenteric vascular engorgement are also noted. (From Chung SY, Ha HK, Kim JH, et al: Radiological findings of Behçet's syndrome involving the gastrointestinal tract. *Radiographics* 21:911-924, 2001.)

Figure 34-146. Behçet's syndrome with bowel perforation. CT scan shows intraperitoneal fluid collection and mesenteric infiltration (arrowheads) surrounding the involved bowel loop (arrow). (From Ha HK, Lee SH, Rha SE, et al: Radiologic features of vasculitis involving the gastrointestinal tract. *Radiographics* 20:779-794, 2000.)

cause bowel ischemia by diminishing splanchnic flow or by stimulating the renin-angiotensin axis, leading to vasoconstriction. Other drugs causing bowel ischemia include various diuretics, antihypertensive medications, and ergot alkaloids.

Chemotherapeutic agents also produce GI toxicity ranging from mild clinical symptoms to acute surgical conditions due to peritonitis, perforation, or bowel necrosis. A high incidence of necrotizing lesions of the GI tract in patients with malignancy, lymphoma, or leukemia has been reported.

Dosik and associates,¹²⁸ separated 26 patients with malignancy (most received antineoplastic and antimicrobial regimens and died of necrotizing colitis) into three histologically distinct categories: (1) those with pseudomembranous colitis (69%), (2) those with agranulocytic (typhlitis) (19%), and (3) those with ischemic colitis (12%).

Amromin and Solomon⁸ also classified necrotic enteric lesions (necrotizing enteropathy) in 63 patients with treated leukemia or lymphoma into the following four types according to the pathogenic mechanisms:

1. Shock with a superficial variety of necrosis.
2. Therapeutic necrosis of tumor or leukemic infiltrates of the intestinal mucosa.
3. Hemorrhage with necrosis of GI mucosa.
4. Traumatic erosions.

In their second group of patients, necrosis occurred at sites with the most abundant lymphoid tissue and, therefore, the terminal ileum or appendix was commonly involved. Because little or no supporting tissue remained, either normal or neoplastic, perforations and peritonitis were common in this group of patients.

Among various chemotherapeutic agents, 5-fluorouracil and its analogs are considered to be the most injurious.³⁴⁷ Ischemic enteritis or enterocolitis can be seen in patients with intra-arterial infusion of floxuridine for the treatment of hepatic metastasis.^{282, 469}

Even though numerous reports regarding the clinical and surgicopathologic aspects of drug-induced enteropathy have been published, studies of imaging results have been limited. This is attributable to the fact that in patients with mild GI symptoms during or following drug therapy of any kind, CT is not usually performed and may be confined to patients with severe symptoms. Furthermore, as symptoms develop with periods of varying intervals after therapy, abnormal CT findings may be commonly confused with other conditions. In our experience, CT findings of drug-induced enteropathy appear to be nonspecific, including mild small-bowel fold thickening, focal or diffuse bowel wall thickening, bowel obstruction, pneumatosis intestinalis, and signs of peritonitis (Figs. 34-147 and 34-148). Therefore, drug-induced enteropathy may be difficult to distinguish from ischemic or inflammatory bowel diseases. Multifocal involvement or patchy distribution in the GI tract may be one of the important features for suggesting the diagnosis.

Radiation Enteritis

Radiation enteritis is generally observed in patients who receive abdominal and pelvic radiation with doses of 4500 to 6000 rads (45 to 60 Gy).⁵¹⁸ The latent period between radiation therapy and the development of radiation damage is usually 6 to 24 months, although this interval can be longer than 20 years. Predisposing factors include diabetes, hypertension, atherosclerosis, prior abdominal surgery with adhesive bowel loops, and peritonitis before the radiation therapy.

The long-term effects of radiation on the vasculature may cause the involved vessel wall, especially of the small arterioles in the submucosa, to be obliterated with sufficient luminal narrowing, resulting in progressive occlusive vasculitis and diffuse collagen deposition with fibrosis.⁵³⁸ Fewer than 2% of patients who receive radiation therapy

Figure 34-147. Chemotherapy-induced enteropathy with diffuse intestinal necrosis in a patient who received chemotherapy for central nervous system lymphoma. A, CT scan shows extensive intrahepatic portal venous gas. B, CT scan shows intestinal pneumatosis (asterisks) and gas in the mesenteric vascular branches. (From Rha SE, Ha HK, Lee SH, et al: CT and MR imaging findings of bowel ischemia according to the various primary causes. *Radiographics* 20:29-42, 2000.)

Figure 34-148. Chemotherapy-induced enteropathy with bowel necrosis and perforation in a patient receiving chemotherapy for leukemia. CT scan shows bowel wall thickening (*arrows*) of the ileum with free gas (*curved arrow*) in the pelvic cavity. Note the intraperitoneal fluid collection, which proved to be hemoperitoneum at surgery. (From Rha SE, Ha HK, Lee SH, et al: CT and MR imaging findings of bowel ischemia according to the various primary causes. *Radiographics* 20:29-42, 2000.)

ultimately require surgery because of perforation, bleeding, fistula, or stricture formation.⁶¹ Although the involved bowel segments depend on the radiation mantle selected, the sigmoid colon, rectum, and terminal ileum are the most common sites affected by chronic radiation enteritis.

The diagnosis of chronic radiation enteritis is difficult because patients often present many years after treatment and the disease often simulates recurrent cancer or adhesion. CT findings of radiation enteritis are relatively non-specific. CT may demonstrate a masslike confluence of adherent bowel loops with thickening of the bowel wall, thickening of adjacent mesentery, or increased density of

Figure 34-149. Acute radiation enteritis in a patient with a history of radiation therapy for periureteral metastases from rectal cancer. CT scan shows bowel wall thickening (*arrows*) of the ileal loops, with the target appearance confined to the radiation port. (From Rha SE, Ha HK, Lee SH, et al: CT and MR imaging findings of bowel ischemia according to the various primary causes. *Radiographics* 20:29-42, 2000.)

Figure 34-150. Perforated radiation enteritis in a patient with a history of radiation therapy for cervical cancer. CT scan shows bowel wall thickening of the ileum with a large amount of ascites and free gas (not shown).

mesenteric fat (Figs. 34-149 and 34-150).¹⁵⁹ The important CT findings that help to differentiate chronic radiation enteritis from other conditions, such as recurrent malignant disease, include the distribution of changes within the radiation therapy port and the absence of a mass.

Large Intestine

Techniques and Normal Anatomy

The imaging protocols for achieving an adequate opacification and distention of the colon are variable, depending on the preferences of the radiologist, the time available for scanning, the types of contrast material used, and the purpose of the examination. Although we prefer a dilute (2% to 3%) barium suspension, the use of dilute iodinated contrast material is safer in patients with trauma or suspected bowel perforation. Patients with suspected enterovesical fistula should undergo pelvic imaging after administration of oral and rectal contrast medium but before administration of IV contrast medium.²⁶¹ This sequence may help to confirm the visualization of small amounts of oral contrast agent entering the bladder via a fistulous tract before the filling of the bladder with the contrast agent.

In general, administration of 400 to 600 mL of oral contrast material is given the evening before or 2 to 3 hours before CT scanning. Alternatively, the patient drinks 450 mL of contrast material 45 minutes before the CT procedure and ingests a tablet of metoclopramide, which hastens the transit of the oral contrast material through the small bowel. The use of metoclopramide eliminates the need for administration of oral contrast material on the evening before the examination and is recommended for outpatients and for emergency studies in inpatients.

The more proximal small bowel is opacified by taking a second cup of 450 mL of contrast agent 30 minutes before the examination. Immediately before CT scanning, another 250 mL of contrast agent is given to fill the stomach and duodenum. Air insufflation per rectum is another useful means of distending the colon.⁴⁰⁰ It allows

accurate assessment of bowel wall thickness and detection of small intraluminal lesions. However, the air insufflation technique should not be used in patients with suspected perforation, clinically severe forms of colitis, radiation enterocolitis, or profound neutropenia.²⁶¹ A rectal contrast enema (200 to 500 mL) or air insufflation can be selectively used for the maximal distention of the distal colon and rectum. An injection of 1 mg of glucagon may reduce the colonic spasm, allowing more accurate assessment of bowel wall thickness through the maximum distention of the colorectum. Vaginal tampons are helpful to delineate the anatomic structures of the lower pelvis in women.

IV contrast material is now used in patients with suspected colonic pathology almost routinely regardless of inflammatory, vascular, or neoplastic diseases because an analysis of the contrast enhancement pattern of the involved bowel often suggests the diagnosis. Use of thin sections may reduce partial-volume averaging, allowing more accurate assessment of bowel wall thickness and extent of disease. Moreover, thin-section CT enables excellent multiplanar reformations.

A total of 150 mL of IV contrast agent is generally used at an injection rate of 2 mL/second. The entire abdomen and pelvis should be scanned in patients with suspected or proven colonic malignancy because many patients have metastatic intra-abdominal disease. In selected cases, and often in patients with recurrent colonic neoplasms in which the main focus may be the liver and upper abdomen, a dedicated liver protocol is obtained with thin axial sections through the liver.

On CT, the colon is visualized by its anatomic location and its typical haustral morphology. It appears as a ringlike or tubular structure, depending on the orientation and position relative to the scanning plane. Recognition of the cecum is facilitated by visualization of the terminal ileum, ileocecal valve, or appendix. The appendix appears as a small ringlike or tubular structure. The presence of air or contrast material in the appendix along with normal-appearing surrounded fat may not be indicative of appendicitis. The ascending and descending colons are within the anterior pararenal space and usually are surrounded by homogeneous fatty tissue. The transverse colon is suspended within the peritoneal cavity by the transverse mesocolon.

The rectum is about 12 to 15 cm in length. The peritoneum covers the anterior surface of the upper rectum, and the lower two thirds of the rectum is enveloped by extraperitoneal connective and adipose tissue. Within the subperitoneal space, a fascial plane (perirectal fascia) encloses the perirectal fatty tissue and separates it from the more peripherally located pararectal connective tissue.

The degree of development of the perirectal fascia varies among individuals, and it is rarely seen in normal patients. Thickening of perirectal fascia helps in early CT recognition of inflammatory or neoplastic involvement of perirectal and pararectal spaces.¹⁹⁴ The colon is commonly filled with fecal material that appears as gas-containing structures and often mimics a soft tissue mass. In certain instances, repeated CT with the patient in various positions may be required to differentiate fecal material from a polypoid colonic mass.

The wall of the normal colon measures 3 mm or less in

thickness when the colon is distended with oral contrast material. Walls measuring between 4 and 6 mm in thickness suggest pathology, and a thickness of more than 6 mm is definitely abnormal. When the air-contrast technique is used, however, measurements of 3 mm for the rectum and 2 mm for the colon are at the upper limit of normal.⁶²² The luminal margin is usually smooth, being well outlined on the mucosal side by contrast or air. The outer colonic margin is sharply outlined by surrounding homogeneous pericolic fat. Inflammation adjacent to the colonic wall obliterates the sharpness of the outer colonic margin by increasing the density of the pericolic fat.

Benign Tumors

Adenoma

Hyperplastic or adenomatous polyps are the most common benign neoplasms of the colon. Because of their small size (<1 cm), however, imaging studies may play no role for the detection. In patients with larger polyps, CT may help in identifying these lesions, but no specific findings to distinguish adenocarcinoma have been reported. According to one series,¹⁰¹ villous adenomas may have a characteristic CT appearance as a result of their high mucus content, producing a soft mass containing homogeneous low attenuation (Fig. 34–151).

Lipoma and Teratoma

Lipoma of the colon is a benign neoplasm arising from the submucosal layer of the intestinal wall. Lesions may be asymptomatic but may cause symptoms when they are large (>2 cm), especially in cases associated with intussusception or ulceration of the overlying mucosa. Seventy percent of the lesions are located in the right colon and usually in the cecum.⁸² They are well demonstrated on CT scans because the masses present characteristic fatty attenuation. However, small lesions may be missed because of artifacts and mostly partial-volume averaging. Further-

Figure 34–151. Villous adenoma with focal malignant transformation. A large polypoid mass (arrows) with heterogeneous contrast enhancement and a lobulated surface is seen in the rectum. Small vessels (arrowheads) supplying the pedicle are also visible within the mass.

Figure 34-152. Colonic lipoma with focal fat necrosis. There is evidence of colocolic-type intussusception with a lipoma at the lead point. A focal area of high attenuation (arrows) in the lipoma results from focal fat necrosis.

more, the intussuscepted lipomas occasionally show focal or diffuse areas of soft tissue attenuation within the lesion and may be mistaken for other neoplasms (Fig. 34-152).

The changes in CT attenuation in such cases are directly related to the degree of infarction and fat necrosis within the lipoma.⁶⁷ Although uncommon, teratoma can occur in the colon. CT may show a mass made up of fatty and soft tissue components.⁵³⁵ The presence of calcification may distinguish teratoma from lipoma.

Hemangioma

Diffuse cavernous hemangioma of the colon is an uncommon disease that affects mainly young adults. The rectosigmoid is the most common site in the GI tract. Chronic rectal bleeding is the main complaint of these patients. On gross examination, an extensive network of vascular lakes is found, involving the entire intestinal wall with infiltration into the surrounding connective tissue. On microscopic examination, the disease is characterized by large, thin-walled vessels with smooth muscle fibers and connective tissue stroma in a submucosal location.⁹⁹

CT may show a transmural thickening of the involved segment, intramural and extrarectal phleboliths, vascular engorgement within the mesentery, and extrarectal lesions (Fig. 34-153).⁴⁵⁸ MRI shows a markedly thickened rectosigmoid wall of very high signal intensity on T2-weighted images, which may result from slow flow in the vascular malformation and is considered to be a highly specific finding. Perirectal fat is also of very high signal intensity on T2-weighted images and exhibits heterogeneity related to serpiginous vascular structures.³⁶⁰

Cystic Lymphangioma

Cystic lymphangioma rarely occurs in the colon as a submucosal lesion. CT may show a sharply margined, a

Figure 34-153. Hemangioma of the rectum. The bowel wall of the rectum (R) is concentrically thickened with poor contrast enhancement. Small phleboliths (arrows) are noted in the involved rectal wall as well as in the perirectal space.

multilocular, or a purely cystic mass.⁶¹⁸ Colitis cystica profunda may also have similar appearances on CT.

Colorectal Carcinoma

Primary Tumors

The ultimate goal of CT and MRI is to predict three factors that affect the patient's prognosis, including:

1. The depth of tumor penetration into the colonic wall.
2. The presence of regional or distant lymph node metastases.
3. The occurrence of distant metastases to other sites.

Except for the advanced colorectal tumors, CT and MRI have virtually no role in the initial diagnosis. On CT and MRI, a colorectal cancer appears as a discrete mass (Fig. 34-154) or focal wall thickening. Asymmetrical wall thickening with or without an irregular surface suggests a neoplastic process.

Generally, CT attenuation on contrast-enhanced scans correlates with tumor size but not with histologic type.²⁶ However, some series have shown that mucinous adenocar-

Figure 34-154. Polypoid rectal carcinoma. CT scan shows a large polypoid mass (arrows), with a lobulated contour, protruding into the rectal lumen.

Figure 34-155. Rectal cancer in the proximal colon in a patient with colitis. CT scan shows a mass (M) in the sigmoid colon along with proximal colonic dilatation. Bowel wall thickening with a target appearance (arrows), also shown in the proximal sigmoid colon, was confirmed as ischemic colitis on pathologic examination. Note the skipped area between tumoral and ischemic segments. (From Rha SE, Ha HK, Lee SH, et al: CT and MR imaging findings of bowel ischemia according to the various primary causes. *Radiographics* 20:29-42, 2000.)

cinoma was enhanced in a peripheral or heterogeneous, lacelike pattern as a result of excessive accumulation of extracellular mucin.²⁵⁰ The presence of punctate or irregular calcifications within tumors may suggest the possibility of mucinous adenocarcinoma. Although rare, ossification may develop in the colorectal tumor.³⁵ In the area of the lower rectum and anus, internal hemorrhoids must be distinguished from a polypoid malignancy.

In 1% to 7% of cases of colorectal carcinoma, ischemic colitis may develop in the proximal colon. An understanding of this condition is important because the concomitant presence of an ischemic segment may give a false impression regarding tumor length or depth of tumor invasion. According to one series,³⁰⁴ CT distinguished ischemic from tumoral segment in 75% of patients by the differences of both bowel wall thickness and contrast enhancement patterns (Fig. 34-155). In contrast to irregular thickening in the tumoral segment, the ischemic segment shows smooth and regular thickening; the target sign with low attenuation in the central zone was the most specific sign. Maximum thickness also differed, with a mean thickness of 2 cm in the tumoral segment and 1 cm in the ischemic segment.³⁰⁴ In certain instances, the ischemic segment may be present in the proximal colon with intervening normal-appearing colonic mucosa.

In another series,²⁸⁸ distal small bowel was affected in 10% of patients' with right-sided colon cancer, especially the tumor involving the ileocecal region. The presence of both colonic and distal ileal thickening might be misinterpreted as inflammatory bowel disease or another neoplastic condition such as lymphoma, when CT imagers are not aware of a patient's history of colon cancer. The distal ileal involvement is caused either by direct tumor invasion or lymphatic spread or by non-neoplastic processes with edema and congestion (Fig. 34-156). Although a target sign in the thickened ileal wall favored the diagnosis of tumor extension, difficulty was encountered in differentiating tumoral from nontumoral involvement.²⁸⁸

Perforation occurring in 2.5% to 8% of patients with colorectal cancer is regarded as a poor prognostic sign. Because perforation is usually either localized or channeled into a fistulous tract, a significant percentage of patients with perforated colorectal cancer have no signs or symptoms of acute toxicity.²⁴⁶ Except for the detection of enteroenteric fistulas, CT proved superior to barium studies in establishing the correct diagnosis. On CT scans, most of these patients showed a neoplastic mass with fluid-attenuation abscess or inflammatory changes in the pericolic or perirectal tissues (Fig. 34-157).²⁴⁶

The patterns of regional spread of disease in the lymph nodes may be predictable on CT. Left-sided colonic and rectal tumors tend to spread first to nodes in the mesocolic, left colic, and inferior mesenteric artery nodal groups.¹⁹⁶ Right-sided colonic tumors tend to spread first to lymph nodes at the root of the SMA and then into the retroperitoneum and to ascend along the paraaortic and aortocaval nodal groups.³⁸⁹ Tumors of the hepatic flexure and proximal transverse colon initially spread to the paracolic nodal group and the nodes of the gastocolic trunk, whereas distal transverse colon and splenic flexure tumors spread to nodes in the mesocolon along middle colic vessels.³⁸⁹ Low rectal or anal tumors drain into the inguinal nodes.

Tumor Spread

When the tumor is confined to the wall of the colorectum, the outer margins of the large bowel appear smooth on CT scans and the perirectal or pericolic fat has uniform low attenuation without soft tissue stranding. Extension of tumor beyond the bowel wall manifests as a mass with irregular outer borders with soft tissue stranding in the perirectal or pericolic fat plane. Similar strandings can also be caused by fibrosis, inflammation, or congestive changes, and CT cannot detect microscopic invasion of the fat surrounding the colorectum. Therefore, a diagnosis of tumor invasion can be confirmed only when a tumor mass extends directly into an adjacent muscle (levator ani, obturator internus, coccygeus, piriformis, or gluteus maximus), obliterating the fat planes and enlarging the individual muscle or enveloping the neighboring structure (Figs. 34-158 through 34-160). In fact, the accuracy of conventional CT for detecting local tumor extension is not high (range, from 55% to 72%).^{26, 170, 577} Accuracy increases with more advanced stages of disease, and most errors with CT have tended to overstage the tumors. Use of colonic preparation, air insufflation, water enema, and helical CT may improve the results to a certain degree.¹⁰

Several studies have evaluated the value of MRI in tumor staging. Major advantages of MRI are that tissue contrast is high and images can be obtained in multiple planes. Extension of tumor beyond the colonic wall is visible on T1-weighted images. Gadolinium enhancement can improve definition of tumor margins.

The reported sensitivities of MRI in staging perirectal invasion varies from 59% to 100%, depending on the method of examination technique. MRI would be equal or inferior to CT with the body-coil MR technique,⁶²⁴ slightly better with the double-surface coil, and much better with the endorectal surface coil.⁵²⁷ The most valuable merit of endorectal surface coil with T2-weighted MRI is its ability

Figure 34-157. Perforated colon cancer. The colonic wall at the hepatic flexure is irregularly thickened (asterisks), and its continuity is focally disrupted (arrowheads). A hypoattenuated mass is formed in the adjacent hepatic parenchyma.

Figure 34-158. Sigmoid colon cancer with bladder invasion. CT scan shows irregular bowel wall thickening of the sigmoid colon (arrows). The superior part of the bladder (B) is irregular because of direct tumor invasion.

Figure 34-159. Rectal cancer with uterine invasion. CT scan shows a large heterogeneous rectal mass (M) with compression and direct invasion into the posterior wall of the uterus (U).

to discriminate the different layers of rectal wall; however, there is a tendency to overstage the lesion.⁵²⁷

Lymph Node Metastases

The detection of local adenopathy depends on nodal size, number, and clustering. Generally, lymph nodes measuring 1 cm or larger and clusters of three or more smaller nodes are considered abnormal. However, CT and MRI cannot distinguish hyperplastic and malignant nodes and cannot detect microscopic nodal involvement. Therefore, the reported sensitivity of CT and MRI is low (25% to 73%).^{10, 26, 527, 577, 624} Thus, no currently available imaging modality may be used to identify, with certainty, lymph node involvement.⁶² However, any nonenhancing nodes in the perirectal fat should be considered malignant lymphadenopathy, regardless of size, because hyperplastic lymph nodes do not occur in this region.

Distant Metastases

Hepatic metastases are the most common site of hematogenous spread in colorectal cancer and appear as areas

of low attenuation on CT. Punctate or amorphous calcification can be seen in the hepatic metastasis from mucinous colonic adenocarcinoma.

Dynamic studies using helical CT scanning may demonstrate varying appearances over time.⁵⁷³ In the early phase, a contrast-enhanced and complete peripheral ring can be seen. If the scan is repeated in the portovenous phase, the lesion itself may enhance with a heterogeneous pattern or target lesions may become evident. Isoattenuation due to “fill-in over time” is the major cause of false-negative CT results in patients thought to have hepatic metastasis. Such lesion isoattenuation is particularly frequent, with smaller masses smaller than 2 cm and conventional, nonhelical CT scanners.

Sometimes a metastasis can appear identical to a simple benign cyst, an eosinophilic abscess, a granuloma, or a hemangioma. According to the surgical literature,⁶⁰⁴ liver resection for hepatic metastases is considered if screening CT shows lesions only in one lobe of the liver as long as only one to four metastases are detected, no other lesions are present in the normal-appearing lobe, the lobe without lesions shows normal function, no focal adenopathy is identified, and no distant spread is evident. If results are equivocal, at least two imaging modalities should be used to exclude the presence of hepatic metastases.

Tumor Recurrence

Local recurrence of a rectal or sigmoid colon carcinoma is often encountered after surgery; it develops during the first 12 months in 50% of patients and within 24 months in more than 80%.⁵⁷² CT is highly sensitive in detection of pelvic masses, but lack of specificity limits its application (Figs. 34-161 and 34-162). The sensitivity of CT in diagnosis of local recurrence is greater in patients with abdominoperineal resection than in those with anterior resection.⁴⁰²

Findings indicative of tumor recurrence include invasion of surrounding structures (muscle, bladder), enlarged local lymph nodes, or a rounded soft tissue mass increasing in size on follow-up scans. Another important sign indicating recurrence is the presence of ischiorectal fossae invasion (Fig. 34-163).⁵⁰⁰

According to one series,²⁸⁴ a soft tissue mass commonly develops in the presacral space or in the area of surgical

Figure 34-160. Ascending colon cancer (not shown) with duodenal invasion. CT scan shows heterogeneous duodenal wall thickening (asterisk) along with lymphadenopathy (n) in the retroperitoneum and peripancreatic region.

Figure 34-161. Recurrent rectal cancer following abdominoperineal resection. A well-enhancing soft tissue mass (M) is seen in the presacral space posterior to the prostate gland.

Figure 34-162. Postsurgical fibrosis following abdominoperineal resection for rectal cancer. A round, well-enhancing soft tissue mass (arrows) is seen in the presacral space.

bed as a result of postoperative fibrous tissue, a displaced uterus or prostate gland, and nonopacified loops of small bowel. However, CT cannot accurately distinguish fibrosis from tumor recurrence (see Figs. 34-161 and 34-162).^{283, 323} Because a single CT examination has an inherent limitation in suggesting the correct diagnosis, it is recommended that a baseline CT scan be performed 3 to 6 months after surgery to observe the evolution of changes in the operative bed and to detect early local recurrence in asymptomatic patients.²⁸⁴

MRI has been advocated as an alternative imaging method for the early assessment of tumor recurrence. An early study suggested that signal intensity on T2-weighted images was accurate in distinguishing tumor from fibrosis.³¹⁰ However, later studies have suggested that high signal intensity on T2-weighted images is not specific for recurrent tumor and can be seen in non-neoplastic, inflammatory changes or edema or in immature fibrosis that develops less than 1 year after surgery.¹¹⁷ Moreover, low signal intensity can be found in both fibrosis and tumor with desmoplastic reaction.¹¹⁷ In this regard, contrast-enhanced MRI, especially dynamic studies, may improve the results, although further investigation is required.^{374, 418}

Figure 34-163. Perineal recurrence of rectal cancer following abdominoperineal resection. A heterogeneous soft tissue mass (M) extends to the left ischioirectal fossae.

Figure 34-164. Mucinous adenocarcinoma of the rectum. CT scan shows a large heterogeneous mass (M) with areas of cystic components. Note marked luminal narrowing of the rectum (arrow).

Mucinous Adenocarcinoma

Colorectal mucinous carcinoma has been regarded as a subtype of adenocarcinoma, with abundant extracellular mucin contained within the tumor. According to World Health Organization criteria for mucinous carcinoma, the mucin composition should be at least more than 50% of the tumor area for the diagnosis.⁶¹⁶ Compared with nonmucinous tumors, mucinous tumors are at a higher pathologic stage at diagnosis, have a greater tendency for metastasis and local recurrence, and carry an unfavorable prognosis.³⁶¹

On CT scans, these tumors may show lower attenuation and commonly demonstrate intratumoral calcification than nonmucinous types (Figs. 34-164 and 34-165). On MR images, signal intensity is higher as a result of the presence of extracellular mucin.^{250, 296} A peripheral or heterogeneous, lacelike contrast-enhancement pattern has been reported to be characteristic of these tumors.²⁵⁰

Figure 34-165. Development of mucinous colonic carcinoma in a patient with juvenile polyposis. A large mass (arrows) in the ascending colon contains multiple calcifications.

Primary Signet Ring Cell Carcinoma

Primary colorectal signet ring cell carcinoma is a rare condition, constituting between 0.1% and 2.4% of all colorectal carcinomas.¹⁴² In the GI tract, it usually produces minimal mucosal alterations but permeates the wall extensively, thereby transforming the affected organ into a rigid and contracted structure. Therefore, this disease is also known as a *linitis plastica* type of carcinoma.

Compared with ordinary colorectal adenocarcinoma, signet ring cell carcinoma commonly occurs in younger patients and tends to spread to the pelvic lymph nodes, the ovaries, and the peritoneal surfaces with a low incidence of hepatic metastasis.⁷ Moreover, its clinical course is aggressive, with a high incidence of local recurrence.⁷

Radiologically, it mimics an inflammatory lesion rather than a carcinoma owing to the long length of involvement. On CT scans, the most common feature of this tumor is a long segment of concentric bowel wall thickening (Fig. 34-166).²⁹⁰ When the rectum is involved, extension to the level of anal verge is common.

Another important CT feature includes target appearance in the thickened colorectal wall. The inner zone of thickened bowel wall with target sign is markedly enhanced owing to abundant fibrous tissues secondary to desmoplastic response. However, these atypical features, such as long length of bowel wall thickening and target appearance, have been noted in approximately 50% of cases with signet ring cell carcinoma.²⁹⁰

Because of its long length of bowel wall thickening, primary colorectal signet ring cell carcinoma may simulate many other conditions; among those, metastatic linitis plastica from stomach, breast, gallbladder, bladder, or pros-

tate¹⁴⁹ may have exactly the same CT appearance.²⁰⁵ Therefore, without knowledge of the clinical history of tumor at other sites, CT differentiation of these two conditions may not be possible. Other conditions that should be considered in the differential diagnosis are lymphoma and inflammatory and vascular disorders (e.g., Crohn's disease, ulcerative colitis, pseudomembranous and ischemic colitis) and gynecologic diseases (e.g., endometriosis, actinomycosis).

Metastatic Tumor

As seen in the stomach and small bowel, metastatic disease can occur in the colon as a result of peritoneal seeding, direct invasion, and hematogenous or lymphatic spread. CT helps not only in discriminating primary from secondary neoplasms to the colon but also in identifying the primary tumor in other sites. The rectum may be affected by direct extension of tumor from the prostate or cervix. Secondary involvement by extension along mesenteric reflection is seen in the transverse colon where neoplasms of either gastric or pancreatic origin extend to the colon. The anterior wall of the rectum is the most common site of peritoneal seeding; other locations include the sigmoid and transverse colons and along the paracolic gutters.

Although not common, hematogenous metastases, especially from breast, melanoma, or lung cancers, produce polypoid masses in the colon and even cause intussusception.⁵⁴⁴ In such instances, it may be difficult to differentiate mucosal polyps from primary colonic tumor. At other times, metastatic tumors may show diffuse involvement of the colonic wall with an annular or linitis plastica appearance on CT, mimicking primary colonic carcinoma or inflammatory bowel disease (Figs. 34-167 and 34-168).

Figure 34-166. Primary "signet ring" cell carcinoma of the rectum. **A**, CT scan shows concentric bowel wall thickening (arrows) with the "target sign" in the rectum. **B**, Double-contrast barium enema shows a long segment of concentric luminal narrowing (arrows) along the rectum with minimal irregularity of the mucosal surface.

Figure 34-167. Metastatic tumor of the rectum with Krukenberg's tumor of the ovary after gastrectomy for gastric cancer. CT scan shows concentric thickening (arrows) of the rectal wall with the "target sign." The surface of the uterus (U) appears irregular, and there is evidence of a left ovarian mass (K), ascites (asterisk), and focal thickening of the peritoneum (arrowhead). (From Ha HK, Jee KR, Yu E, et al: CT features of metastatic linitis plastica to the rectum in patients with peritoneal carcinomatosis. *AJR Am J Roentgenol* 174:463-466, 2000.)

Such linitis plastica pattern of colonic involvement may result from the intramural spread of tumor cells through the submucosa or subserosa in association with bowel peristaltic movement.¹⁴⁹ Because an important pathologic characteristic of linitis plastica is the exuberant desmoplastic reaction in the submucosa and subserosa, the occurrence of a target sign in diffusely thickened wall is commonly seen on CT scans.²⁰⁵

Gastrointestinal Stromal Tumors

Stromal tumors occur rarely in the colorectum, with the rectum a more common site than the colon. These tumors appear as a submucosal mass growing toward the lumen (endocolic), away from it (exocolic), or in a combined (dumbbell) form. In certain instances, a constricted form occasionally has also been reported.⁴⁹¹ In general, clinical

Figure 34-168. Metastatic linitis plastica involving the ascending colon in a patient who had undergone gastrectomy for gastric cancer. CT scan shows marked luminal narrowing of the ascending colon with concentric bowel wall thickening (arrows) in addition to the "target sign" markedly enhancing the inner zone.

symptoms correlate with the types of tumor growth: *intramural* types cause pain, bowel habit changes, and intestinal obstruction; *pedunculated* tumors commonly develop intussusception or bleeding owing to degeneration; and *exocolic* tumors may have a common occurrence of peritoneal metastasis.⁵⁵⁴

Seventy percent of rectal stromal tumors are located in the lower rectum, 20% are in the midrectum, and 10% are in the upper rectum. In the remaining part, these tumors are located equally in the ascending colon, the transverse colon, and the descending colon.⁵⁵² Because of the high incidence of late recurrence, some investigators suggest that most colorectal stromal tumors should be regarded as potentially malignant neoplasms.⁵⁹³

Generally, stromal tumors have varying degrees of internal necrosis or cystic changes on CT, predominantly in cases of malignant forms (Fig. 34-169). The presence internal dystrophic calcification within a tumor suggests the possibility of stromal tumor in the colon, although this finding can be seen in both benign and malignant forms (Fig. 34-170). The tumor growth patterns may be helpful in differentiating the benign from malignant form; endophytic tumor growth favors the diagnosis of benign rather than malignant form.⁹³

Stromal tumors arising from the rectum may be difficult to diagnose preoperatively. Many possibilities occur in considering the differential diagnosis, depending on the patient's gender or the direction of tumor growth. Tumors growing in an *anterorectal* direction may be easily confused with prostatic and gynecologic tumors, such as uterine, cervical, and ovarian tumors or a mass arising from the rectovaginal septum. Stromal tumors growing in the *retrorectal* direction should be differentiated from other unusual sarcomas or lymphomas.

In contrast with cases of rectal cancer, rectal stromal tumors usually show an absence or mild degree of obstruction owing to the position of the main tumoral component in the extraluminal space.¹⁵ Except for its poor sensitivity for detection of internal tumoral calcification, MRI may be

Figure 34-169. Rectal leiomyosarcoma. CT scan shows a heterogeneous mass (arrows) of rectal (R) origin growing exophytically and displacing the vagina anteriorly. (From Lee SH, Ha HK, Byun JY, et al: Radiological features of leiomyomatous tumors of the colon and rectum. *J Comput Assist Tomogr* 24:407-412, 2000.)

Figure 34-170. Rectal leiomyosarcoma. CT scan shows a calcified mass (arrows), anterior to the rectum (arrowhead), simulating a prostatic mass. (From Lee SH, Ha HK, Byun JY, et al: Radiological features of leiomyomatous tumors of the colon and rectum. *J Comput Assist Tomogr* 24:407-412, 2000.)

comparable to CT in evaluating the morphology of the tumors.³²⁶

Lymphoma

Primary lymphoma of the colon is relatively rare, constituting approximately 0.05% of all colonic neoplasms and fewer than 3% of all extranodal lymphoma.¹²⁴ Non-Hodgkin's lymphoma is the most predominant type, and the cecum and rectum are the most common sites of involvement. Colonic lymphoma may be (1) infiltrative, (2) polypoid, (3) cavitory, or (4) diffuse.

On CT, the *infiltrative* form is characterized by a long segment of concentric luminal narrowing by diffuse tumor infiltration into the submucosa, simulating primary colonic carcinoma (Fig. 34-171). However, in patients with lymphoma, the occurrence of aneurysmal dilatation is common, and the degree of contrast enhancement of the mass is usually poor owing to a lack of desmoplastic reaction.

CT may not distinguish a *polypoid* form of lymphoma from primary colonic adenocarcinoma (Fig. 34-172). However, lymphoma may be a possibility when the tumor

Figure 34-171. Colonic lymphoma. Bowel wall of the ascending colon (arrows) is irregularly thickened.

extends to the terminal ileum, when diffuse mesenteric lymphadenopathy and splenomegaly are associated, and when the tumor shows no evidence of invasion or obstruction of neighboring viscera.⁶⁰⁷ In the cavitory form of lymphoma, large tumors may excavate into the mesentery, producing a giant cavitated mass.

In the *diffuse* form of lymphoma characterized by multiple nodules of relatively small size, CT may not detect the nodules but helps in staging the tumor.

Mucocele

Mucocele of the appendix is a descriptive term for an abnormal mucus accumulation distending the appendiceal lumen, regardless of the underlying cause. Mucoceles usually result from obstruction of the appendiceal lumen. Both benign and malignant lesions can produce a mucocele, consisting of mucosal hyperplasia, mucinous cystadenoma, and mucinous cystadenocarcinoma.²³³

Preoperative diagnosis is important because of the possibility of rupture at surgery with the development of pseudomyxoma peritonei (described later). On CT, a mucocele appears as a low-attenuation, well-encapsulated mass with smooth, regular walls in the right lower quadrant. The degree of attenuation depends on the amount of mucin in the mass. No periappendiceal inflammation or abscess is the key differential point in excluding acute appendicitis. Calcification occasionally develops in the wall of the mucocele, owing to a dystrophic response to a chronic inflammatory process incited by the mucus; this can ultimately lead to a *porcelain appendix*.¹⁰⁶

Although uncommon, intussusception may develop. *Myxoglobulosis*, a variant of mucocele, is seen in 0.35% to 8% of cases and is characterized by an appendix filled with "translucent globules," or a cluster of "frog eggs."¹⁰⁶ When these spheres calcify, they become evident on CT and may shift in the appendix with changes in body position. The presence of a thickened wall suggests the possibility of a neoplastic mucocele, and enhancing nodules favor the diagnosis of mucinous cystadenocarcinoma (Fig. 34-173).²⁹⁷

Rupture of a mucocele may result in pseudomyxoma peritonei, characterized by implants of mucinous epithelium on the peritoneal surfaces and mucus accumulation within the peritoneal cavity (Fig. 34-174).

Inflammation

Crohn's Disease

Patients with Crohn's disease are at increased risk for colorectal cancer. According to one study,²²³ colorectal cancer occurred an average of 10 years earlier than sporadic cancer and is more often of the mucinous type. Rectal sparing is a characteristic of Crohn's disease that helps distinguish it from ulcerative colitis, but perirectal and perianal lesions occur in up to one third of patients, especially those with colonic involvement.

The most common CT finding of Crohn's colitis is bowel wall thickening (mean thickness, 11 mm).⁴⁶¹ It is often discontinuous and may have skip areas. Although a double-halo appearance of the bowel wall has been re-

Figure 34-172. Colonic lymphoma. *A*, A polypoid mass (M) is seen in the ascending colon. *B*, The mass (M) extends into the terminal ileum.

ported in Crohn's disease involving the small intestine,¹⁶⁷ most patients show homogeneously attenuated bowel wall thickening when the colon is involved (Fig. 34-175).⁴⁶¹ Marked contrast enhancement in the early phase of dynamic study and the presence of hypervascularity in the pericolic space and mesentery may indicate acute exacerbation of the disease. Perianal disorders, which are quite common in patients with Crohn's disease, include anal fissures and ulceration, perirectal abscess, and fistulas.

CT offers an excellent alternative to barium studies in fully defining the extent of perirectal disease, especially in patients with an exquisitely tender perineum or rectum in which the performance of barium enema and sinography is painful (Fig. 34-176).⁴⁹⁴ In performing the CT scan for patients thought to have perianal disease, the scanning plane must continue caudal to the symphysis to include the entire perineum because of common occurrence of diseases

beneath the level of the symphysis pubis.⁶¹⁹ Because of multiplanar capability, MRI is superior to CT in demonstrating the relationship between the pelvic and abdominal sinus tracts or fistulas and the levator ani muscle.³⁰⁷

In the differentiation with ulcerative colitis, Crohn's colitis may show even distribution between right-sided, left-sided, or bilateral disease and high frequency of both small-bowel involvement and abscess.⁴⁶¹ The presence of ascites is not common in Crohn's disease and instead suggests pseudomembranous, infectious, or ischemic colitis. Tuberculous colitis may have patterns of bowel wall changes similar to those of Crohn's disease. In tuberculous colitis, however, the occurrence of rectal involvement is rare; lymph nodes are larger than 1 cm and may show central necrosis. Moreover, the presence of CT findings of peritonitis, such as diffuse omental and mesenteric infiltra-

Figure 34-173. Mucinous cystadenoma of the appendix. A cystic mass (M) is noted in the pericecal region, which shows curvilinear calcification (arrows) in the periphery. The appendiceal wall (arrowhead) is concentrically thickened with minimal periappendiceal infiltrate.

Figure 34-174. Mucinous cystadenocarcinoma of the appendix with pseudomyxoma peritonei. CT scan shows nodular omental infiltration and a large amount of ascites. A cystic mass (arrow) is seen in the pericecal region.

Figure 34-175. Crohn's disease. CT scan shows colonic wall thickening (*arrows*) with a faint demonstration of the "target sign" along with fibrofatty proliferation and prominent mesenteric vessels.

Figure 34-176. Crohn's disease with enterorectal fistula. A, Small-bowel follow-through examination shows an enterorectal fistula (*arrow*). B, CT scan shows diffuse pericolic, perirectal, and perienteric inflammatory infiltrates with bowel wall thickening of pelvic ileal loops. C, Gadolinium-enhanced MR image shows marked contrast enhancement in the thickened rectal wall (*arrows*) and inflammatory tissues (*arrowheads*) surrounding the fistula.

Figure 34-177. Tuberculous colitis. CT scan shows concentric bowel wall thickening (arrows) of the ascending colon with pericolonic stranding and minimal lymphadenopathy (arrow-head).

tion or nodules and ascites, may indicate tuberculous origin.

Tuberculous Colitis

Tuberculous colitis may have several forms, most commonly segmental colitis, inflammatory strictures, and hypertrophic lesions resembling polyps and tumors.³⁷⁵ A rare

form includes a diffuse type simulating ulcerative colitis.¹⁷ The ileocecal area is involved in about 90% of the cases, and there is a decreasing frequency of involvement proximal and distal to the ileocecal valve.¹ Multiple sites of involvement are common with skip segments.⁵⁸⁵ The length of stricture is usually shorter (<3 cm) than that of Crohn's disease.⁵⁶⁵ Tuberculous lymphadenitis adjacent to the colon can result in colonic traction diverticula, bowel fixation, and sinus tract formation.³⁷⁵ Although not common, anal TB may cause ulcers and fissures, fistulas, and abscesses.

On CT scans, the involved colon may show circumferential bowel wall thickening up to 3 cm. This thickening is usually homogenous in attenuation (Fig. 34-177); however, mural stratification (a double-halo or target sign) is rarely seen. Thickening of the ileocecal valve or the presence of inflammatory tissue (localized hypertrophic type), or segmental lesion in any sites of the colon may give the appearance of colonic carcinoma on CT. There are also no specific CT findings that can distinguish from Crohn's disease in the bowel wall involvement patterns, except for the distribution of disease; it is rare to see rectal involvement in tuberculous colitis, and the predominant left-sided colonic involvement may favor Crohn's disease.

Active tuberculous lesions may be suggested on CT in the following circumstances:

1. When there is diffuse inflammatory infiltrates or, rarely, hypervascularity in the pericolonic space.
2. When the enlarged lymph nodes in the pericolonic space or other sites are diffusely enlarged or show central low attenuation.

Figure 34-178. Perforated tuberculous colitis. A, CT scan shows mass-like bowel wall thickening (arrowheads) with colonic obstruction. Ill-defined soft tissue-attenuated lesion is seen in the pericolonic space. There is also evidence of loculated fluid collection (arrow). B, Barium study shows nearly complete colonic obstruction at the hepatic flexure of the colon.

Figure 34-179. Ulcerative colitis. The bowel wall of the rectum and sigmoid colon is minimally thickened with a target appearance (arrowheads).

3. When there is evidence of diffuse peritonitis, such as ascites, infiltration, or nodules in the omentum or mesentery, and peritoneal thickening.

The latter two findings also favor the diagnosis of tuberculous colitis rather than Crohn's disease. Although not common, fibrofatty proliferation can be seen in the pericolonic space. Healing of ileocecal lesions may result in shortening of the ascending colon. In such cases, the thickened terminal ileum may be easily misinterpreted as ascending colon on CT. In comparison with tuberculous enteritis, the incidence of colonic obstruction is low because of a larger luminal diameter in the colon, but it rarely occurs in hypertrophic type of tuberculous colitis. Colonic perforation due to tuberculous colitis is also rare (Fig. 34-178).

Ulcerative Colitis

Ulcerative colitis is characterized by a chronic mucosal disease with the inflammatory reaction that remains limited to the mucosa and the superficial portion of the submucosa. It usually starts in the rectum and then spreads more

proximally, sometimes to involve the entire colon (pancolitis). In about one third of the cases, the ileum is involved by backwash ileitis. In active stages of the process, the mucosa shows a diffuse, uniformly granular, and erythematous, hemorrhagic appearance, and the entire bowel becomes fibrotic, narrowed, and shortened in the advanced stage.

When the disease is limited to the mucosa, the colon appears normal on CT scans; the presence of active ulceration does not significantly alter the CT appearance of the colonic wall. In patients with chronic disease, CT may show bowel wall thickening caused by hypertrophy of the muscularis mucosa and deposition of submucosal fat (Figs. 34-179 and 34-180).¹⁹²

The mean bowel wall thickness is 7.8 mm in ulcerative colitis and 11 mm in Crohn's disease.⁴⁶¹ In about 70% of patients with ulcerative colitis, the thickened bowel wall may show heterogeneous attenuation, with a target appearance due primarily to submucosal fat. This target appearance is most commonly observed in the rectum but less frequently in the remainder of the colon.²⁷¹ Submucosal fat deposition is seen only in the chronic or subacute disease⁴⁶¹ and may result from a long-term use of corticosteroid therapy.

An additional CT feature favoring the diagnosis of ulcerative colitis includes widening of the presacral space, which results from a combination of increased presacral fat deposition, luminal narrowing of the rectum, rectal wall thickening, and stranding of the perirectal fat.²⁶¹ Although rarely seen, pneumatosis may develop in severe ulcerative colitis.⁴⁶¹

MRI may be a new imaging modality in analyzing the mural changes in patients with ulcerative colitis,¹⁷⁹ but further experience is necessary to define its clinical role.

Local complications of ulcerative colitis include perforation with peritonitis and abscess (Fig. 34-181), toxic megacolon (Fig. 34-182), venous thrombosis, and carcinoma (Fig. 34-183). Because the risk of carcinoma is markedly increased in ulcerative colitis with a long-standing history (>10 years) or with pancolitis, CT findings of any focally exaggerated colonic wall thickening with pericolonic

Figure 34-180. Ulcerative colitis. Heterogeneous bowel wall thickening (arrows) is noted in the ascending colon and descending colon. Minimal pericolonic infiltration is noted.

Figure 34-181. Bowel perforation in a patient with ulcerative colitis. The bowel wall (arrows) of the hepatic flexure of the colon is thickened with diffuse pericolic infiltration and fluid collection. Free gas (arrowhead) is also noted.

lymphadenopathy in these patients should suggest the possibility of cancer development. The presence of toxic megacolon should be suspected on CT when the colonic lumen is considerably dilated (>8 cm).¹⁹¹ Typically the bowel wall will be thinner rather than thick.

Diverticulitis

Colonic diverticulosis affects approximately 5% of the population, and acute inflammation occurs in 10% to 35% of these patients.⁸³ Diverticula are primarily caused by obstruction of diverticular neck with fecal material, subsequently resulting in distention and inflammation of the prediverticular tissues. In uncomplicated diverticulitis, the inflammatory process is confined to the colonic serosa. Microscopic perforations into the pericolic fat are usually walled off, forming focal abscesses; however, continued

Figure 34-182. Toxic megacolon in a patient with ulcerative colitis. The transverse colon is markedly dilated (arrows) with nodular mucosal contour.

Figure 34-183. Colonic carcinoma complicating a long-standing ulcerative colitis. The splenic flexure of colon shows irregular bowel wall thickening (arrow) with proximal colonic dilatation caused by obstruction.

infection and inflammation can lead to peritonitis or fistulas. The inflammatory process can also dissect longitudinally within the wall of the colon, giving rise to intramural sinus tracts.

Although not common, diverticulitis also causes large-bowel and small-bowel obstruction,²⁸⁹ portal and mesenteric vein gas,⁵⁹⁹ venous thrombosis, and colovenous fistula to the inferior mesenteric vein.⁵¹⁴ The classic clinical symptoms and signs, especially in sigmoid diverticulitis, include left lower quadrant pain, tenderness, fever, and leukocytosis. Therefore, these signs may mimic many other acute abdominal conditions.

Although barium studies can be used, CT has been advocated as the initial procedure for radiologic evaluation for suspected acute diverticulitis. It is not only more suitable for grading the severity of pericolic inflammation but also more accurately depicts the presence, location, and size of pericolic abscesses.^{90, 470} In addition, the use of CT is more effective in determining the alternative diagnosis.

The sensitivity of CT in diagnosis of diverticulitis is reported to range between 79% and 97%, with a specificity of 77% to 100%.^{90, 270, 470, 484} According to some reports, the use of helical CT with thin-section CT²⁶⁴ can improve the detection of diverticulitis. The most important CT findings of diverticulitis include diverticula, inflammatory bowel wall thickening, and pericolic fat stranding (Figs. 34-184 to 34-186).⁹⁰ More severe cases may depict extraluminal air bubbles, phlegmon, pericolic abscess, colonic fistula and sinus tracts, colonic obstruction, and peritonitis. In some instances, contrast material may collect in an arrowhead shape adjacent to focally inflamed colonic wall (arrowhead sign),⁴⁸⁸ and inflamed diverticulum appears as a thick, enhancing ring shadow within the area of inflamed peridiverticular tissues (see Fig. 34-184).²⁶⁴

A few reports^{87, 446} have indicated an overlap with the imaging appearance of colon cancer in about 10% of cases of diverticulitis. The point of overlap includes colonic wall thickening of more than 1 cm, associated soft tissue mass, wall thickening with luminal narrowing, wall thickening

Figure 34-184. Acute diverticulitis. The inflamed diverticular wall (arrow) appears to be thickened, and there is diffuse mural edema (m) in the adjacent colonic wall. (From Jang HJ, Lim HK, Choi SH, et al: Acute diverticulitis of the cecum and ascending colon: Thin-section helical CT findings. *AJR Am J Roentgenol* 172:601-604, 1999.)

without pericolic inflammation, and short segments of wall thickening.⁸⁷ CT findings favoring the diagnosis of acute diverticulitis include fluid at the root of the mesentery and vascular engorgement.⁴⁴⁶ In contrast, an abrupt zone of transition with normal bowel, enlarged pericolic lymph nodes, and mural thickness greater than 1.5 cm favor colonic carcinoma (Fig. 34-187).⁸⁷

Right-sided diverticulitis represents only about 5% of cases in Western populations but accounts for 17% in Asian patients.³⁵¹ Although CT findings are similar to those of left-sided diverticulitis, it may be difficult to differentiate cecal diverticulitis from appendicitis unless a normal appendix is seen. The presence of an intramural abscess or cecal diverticula, in association with an inflammatory process located cephalad to a normal-appearing cecal caput and the periappendicular region, should suggest the diagno-

Figure 34-186. Diverticulitis after response to antibiotic treatment. CT scan obtained after antibiotic therapy shows only multiple barium-filled diverticula (arrows) and minimal bowel wall thickening without pericolic inflammatory infiltrates.

sis.²⁵ The offending diverticulum may contain gas, fluid, contrast material, or calcified material.²⁶⁴

Appendicitis

Appendicitis is one of the most common causes of acute abdomen. Although the clinical diagnosis is usually made on the basis of history, physical examination, and laboratory data, approximately 20% to 33% of patients with suspected appendicitis present with atypical features.³⁴⁶ Up to 20% negative appendectomy rates have been considered to be acceptable.³⁴⁶

CT is now regarded as the most accurate diagnostic test for excluding appendicitis. The reported diagnostic accuracies of CT range between 93% and 98%, with a sensitivity of 90% to 98% and a specificity of 83% to 98%; alternative diagnostic rates range between 48% and 80%.^{27, 314, 483, 485}

A variety of CT techniques have been used for appendiceal imaging, including unenhanced and contrast-enhanced

Figure 34-185. Diverticulitis of the sigmoid colon. The wall of the sigmoid colon (asterisk) is thickened. A small amount of free gas collection (curved arrow) and infiltrates is seen in the pericolic space.

Figure 34-187. Colon cancer simulating diverticulitis. The sigmoid colon shows concentric bowel wall thickening (arrows) with an abrupt transition between normal and tumoral segments. Pericolic stranding is also noted.

Figure 34-188. Acute appendicitis. The appendix (*asterisks*) is dilated with a thickened wall owing to mural edema. A small appendicolith (*arrow*) is also seen.

CT, conventional and helical CT scanning, full and limited abdominopelvic scanning, and various combinations of contrast materials.^{27, 314, 483, 485} Among various techniques, use of both unenhanced and helical CT scans appear to have some merits.^{314, 483, 485}

The advantage of unenhanced CT scans is that their use can eliminate the risk of an adverse reaction to IV contrast material and is less expensive. Helical CT scans may eliminate the risk of missing the appendix by misregistration; also, relatively thin-section images can be easily obtained. The importance of optimal cecal opacification and distention with contrast material has been stressed.^{483, 485} Contrast material can be administered only through the colon or both by mouth and through the colon; however, each technique shows no statistical difference in achieving high diagnostic accuracy.^{483, 485}

CT features in typical cases of acute appendicitis include an abnormal appendix, periappendiceal inflammation, and changes in the cecal apex. The abnormal appendix is distended and nonopacified, showing a diameter wider than 6

Figure 34-189. Periappendiceal abscess with small-bowel obstruction. A thick-walled, cystic mass (*arrows*) containing high-attenuated appendicolith (*arrowhead*) is seen at the right lower quadrant. Small-bowel loops are diffusely dilated as a result of bowel obstruction.

Figure 34-190. Perforated acute appendicitis with abscess. An abscess (A) with air-fluid level is noted in the root of the mesentery.

mm, wall thickening and enhancement after contrast infusion, and appendicoliths (Figs. 34-188 and 34-189). Periappendiceal inflammatory changes include fat stranding, phlegmon, fluid, free air bubbles, abscess, and adenopathy (Figs. 34-190 and 34-191).

Changes in the cecal apex include focal cecal apex thickening, an arrowhead sign, and a cecal bar; the arrowhead sign indicates a collection of contrast material between each side of the cecal apical thickening, and the cecal bar is a straight or slightly curved band of inflamed soft tissue that separates proximal calcified appendicolith from cecal lumen.⁴⁹⁰ Although highly specific, the presence of appendicolith does not always indicate appendicitis and may be an incidental finding.

Variants of appendiceal disease include (1) recurrent, (2) chronic, (3) stump, and (4) distal appendicitis.

Stump appendicitis occurs after appendectomy with simple ligation without appendiceal stump invagination; the residual stump acts as a small appendix or diverticulum (Fig. 34-192).

Figure 34-191. Acute appendicitis with free perforation into the peritoneal cavity. A large amount of intraperitoneal fluid collection with free gas is present.

Figure 34-192. Stump appendicitis. A small appendicolith (curved arrow) is noted within the appendiceal stump. The wall of the cecum (arrows) is considerably thickened as a result of mural edema. There is also evidence of inflammatory infiltrates in the pericecal fat plane.

Distal appendicitis is a potential cause of false-negative CT results, which may show a normal cecal apex and proximal appendix, a gradual or abrupt enlargement of the distal appendix, and periappendiceal fat stranding.⁴⁸⁶

MRI can also be used in the diagnosis of appendicitis.²⁵⁵ Intense contrast enhancement of the inflamed appendiceal wall indicates the presence of appendicitis. However, MRI has inherent limitations in detecting appendicoliths.

Epiploic Appendagitis

Epiploic appendices (appendices epiploicae) are sacs of visceral peritoneum that are filled with fat and vascular structures and protrude from the serosal surface of the colon. The average person has approximately 100 appendices epiploica that are distributed from the cecum to the rectosigmoid junction. Rarely, epiploic appendages may undergo torsion or spontaneous venous thrombosis with subsequent ischemic infarction and inflammation; this condition is termed *primary epiploic appendagitis*.⁵⁷⁵ The torsion has been reported to be related to heavy exercise or excessive stretching.⁵⁰⁴

Secondary epiploic appendagitis is caused by inflammation of adjacent organs (i.e., in diverticulitis, appendicitis, or cholecystitis).

Patients with primary epiploic appendagitis characteristically present with an abrupt onset of focal abdominal pain, mild fever, and mild elevation of the white blood cell count, which is often mistaken for appendicitis or diverticulitis. Most cases can be managed conservatively with the use of analgesics only.⁴⁸⁹

The diagnosis can be made confidently on CT, and this disease can be differentiated from other, far more common conditions such as appendicitis and diverticulitis. The important CT findings include pericolic, oval-shaped lesions with fat attenuation, thickened peritoneal lining, and periappendageal fat stranding (Fig. 34-193).^{109, 504} Additional findings include a central high-attenuating dot and a thickened nearby parietal peritoneum as well as mass effect, focal wall thickening of adjacent colon, or both. *Omental infarction* may produce similar CT findings, but

Figure 34-193. Appendagitis in patient with left lower abdominal pain and tenderness, mild fever, and leukocytosis. CT scan shows a pericolic, oval-shaped, fatty lesion (arrows) with an enhancing peripheral wall. Pericolic fat strands also surround this lesion.

it appears as a larger lesion without a well-defined rim of thickened visceral peritoneum.

Pseudomembranous Colitis

Pseudomembranous colitis is a potentially life-threatening acute infectious disorder associated with the overgrowth of *Clostridium difficile* after antibiotic use. Although virtually all antibiotics may produce the disorder, clindamycin, ampicillin, and cephalosporins are agents most commonly associated. Most cases occur when the drug is given orally rather than parenterally. Pseudomembranous colitis may also occur in other clinical settings such as bowel ischemia, intestinal obstruction, uremia, abdominal surgery, or chemotherapy.⁵⁰⁹

The disease usually involves the colon but may include only the small bowel or both colon and small bowel. In the colorectum, the rectum and sigmoid colon are typically involved. In approximately 30% to 40% of cases, however, pseudomembranous colitis can be limited to the right side of colon with sparing of the rectosigmoid or even the entire left side of colon.¹⁵⁶

The classic clinical presentation includes abdominal pain, watery diarrhea, fever, and leukocytosis. CT is helpful not only in suggesting the diagnosis but also in evaluating the extent of disease. Common CT findings include colonic wall thickening, low-attenuation mural thickening corresponding to mucosal and submucosal edema, the accordion sign, the target sign, pericolic stranding, and ascites (Figs. 34-194 and 34-195). The average colonic wall thickness (14.7 mm) is nearly twice that reported in the ulcerative colitis and more than that reported in Crohn's disease (7.8 and 13 mm, respectively).¹⁵⁶

The accordion sign indicates alternating edematous haustral folds separated by transverse mucosal ridges filled with oral contrast material. Although this sign was once considered specific for the diagnosis of pseudomembranous colitis,¹⁵⁶ it can be seen in other edematous and inflammatory conditions affecting the colon, such as portal hypertensive colopathy and ischemic colitis.³⁶³ Ascites is seen in

Figure 34-194. Pseudomembranous colitis. CT scan shows marked bowel wall thickening of the sigmoid colon and rectum (asterisk), producing a target appearance. Diffuse pericolic and perirectal infiltration is seen.

approximately 35% of cases.¹⁵⁶ Untreated cases of pseudomembranous colitis can result in toxic megacolon with subsequent perforation and peritonitis. However, CT does not help to distinguish patients requiring surgical intervention from patients requiring conservative management.²⁷⁸

Cytomegalovirus Colitis

CMV is a herpesvirus that can be sexually transmitted or transmitted via infected organs, blood, or needles. CMV remains in a latent state in the host after initial infection. With increasing impairment of cell-mediated immunity, particularly a CD4 lymphocyte count lower than 100 mm³, reactivation may occur.⁵⁹²

Clinically evident CMV infections most commonly affect immunosuppressed patients, including transplant recipients and patients with AIDS. However, CMV infection may occasionally occur in nonimmunosuppressed individuals, including patients with diabetes mellitus, those who receive corticosteroids or radiation therapy, and elderly patients.⁵⁵³

Although the incidence of small-bowel involvement is

Figure 34-196. Cytomegalovirus colitis with bowel perforation. The sigmoid colon shows a thickened wall with a target appearance (arrows). Minimal pericolic strands and a small amount of ascites are noted.

not rare, the colon is the organ most commonly affected by CMV infection. Before the AIDS epidemic, the cecum was the most common site of colonic involvement, but in approximately 50% of patient with AIDS the disease was confined to the descending colon, particularly to the recto-sigmoid region. In severe forms, multiple ulcerations and perforations occur; the vasculitis resulting from the CMV endothelial cell involvement in the wall or submucosal vessels leads to tissue edema and necrosis with ulceration, hemorrhage, and perforation.²³⁴

The clinical symptoms of CMV colitis are persistent diarrhea, fever, weight loss, abdominal pain, and hematochezia. The most prominent CT feature is colonic wall thickening with mural edema and deep ulceration (Fig. 34-196).⁴²⁰ Other findings include pericolic stranding, lymphadenopathy, and ascites. Because of nonspecificity of these findings, it is difficult to distinguish CMV infection from other colitides such as pseudomembranous colitis, although the relative high incidence of small-bowel involvement is a useful feature in this regard.⁴²⁰

Neutropenic Colitis (Typhlitis)

Neutropenic colitis, a necrotizing enterocolitis, occurs as a complication of acute leukemia or other neutropenic states such as aplastic anemia, SLE, or cyclic neutropenia. The cecum is most commonly involved, but the remaining colon and distal ileum may also be affected.

Various factors account for predominant cecal involvement by neutropenic colitis.² The cecum represents an area of relative stasis of bowel contents and is easily distensible. Mucosal ulcerations create a mural port of entry for the resident colonic microflora and allow the overgrowth of bacteria, viruses, or fungi, causing edema, thickening, and induration of the cecal wall.^{2, 247}

Typical clinical features are fever, watery diarrhea, abdominal pain, and occasionally a palpable mass. CT findings are nonspecific and include concentric homogeneous or heterogeneous thickening of the bowel wall with intramural edema and necrosis, pericolic fluid, and pneumatosis intestinalis (Fig. 34-197).¹⁷¹

Figure 34-195. Pseudomembranous colitis. The colonic wall is diffusely thickened from the ascending colon through the rectum. The transverse colon shows the "accordion sign" (arrows).

Figure 34-197. Development of typhlitis during chemotherapy for leukemia. CT scan shows concentric bowel wall thickening (arrows) of the cecum with poor contrast enhancement.

Uncomplicated neutropenic colitis is managed conservatively, if left untreated, neutropenic colitis progresses to transmural necrosis and colonic perforation, requiring surgery.²

Actinomycosis

Actinomycosis is a chronic, progressive, suppurative disease characterized by the formation of multiple abscesses, draining sinuses, abundant granulation, and dense fibrous tissue. This infection is considered to be caused by *Actinomyces* organisms (most commonly, *Actinomyces israelii*), which are gram-positive anaerobic bacteria; they are not regarded as virulent human pathogens and are best considered as opportunistic because they are normally present in healthy individuals, especially in the oral cavity, tonsillar crypts, and colon.⁴⁰ Dental caries are also common reservoirs of *Actinomyces*.³⁹

A. israelii has a world-wide distribution and is present with equal frequency in urban and rural dwellers.⁴⁰ Although that there is no reported discernible sex predilection, most patients (94%) are women.^{40, 612}

Human actinomycosis commonly occurs in three distinct forms. Most cases of clinical disease are *cervicofacial* (55%), with only 20% occurring in an *abdominopelvic* form and 15% as *thoracopulmonic* form.^{39, 612} Abdominopelvic actinomycosis has been associated with abdominal surgery (such as appendectomy), bowel perforation, or trauma. The association with a long-standing intrauterine device has been emphasized as a risk factor in young women.⁴³¹ Various abdominal organs can be involved in abdominopelvic actinomycosis, including the GI tract, ovaries, liver, gallbladder, and pancreas.⁴⁰ In many instances, the GI tract appears to be secondarily involved and the rectosigmoid colon and ileocecal region, including the appendix, are most commonly involved.^{40, 526}

The clinical features depend on which organs are involved, but common symptoms and signs include fever and leukocytosis.^{40, 211} The presumptive diagnosis is made when "sulfur granules" are seen in the Papanicolaou smears of pus in the abscess or discharged material from the sinus tract.²⁰³ Although histologic identification of actinomycotic

Figure 34-198. Actinomycosis. A large, bilobed, heterogeneous mass (arrows) in the ovary and bowel wall thickening of the rectum (R) are seen. (From Ha HK, Lee HJ, Kim H, et al: Abdominal actinomycosis: CT findings in 10 patients. *AJR Am J Roentgenol* 161:791-794, 1993.)

granules or culture of *Actinomyces*⁴⁰ is important to establish a definitive diagnosis, the success rate is fewer than 50% of cases.³⁹

The use of CT in patients with abdominopelvic actinomycosis is important for suggesting the diagnosis and determining the anatomic location and extent of disease as well as for monitoring the effectiveness of treatment and for follow-up in cases of possible recurrence.^{211, 225}

Because of their aggressiveness and infiltrative nature, this disease can easily be mistaken for GI malignancy on CT scans, including carcinoid tumor, intestinal TB, Crohn's disease, diverticulitis, and other complicated GI infections. When the GI tract is involved, the main CT features include bowel wall thickening (mostly concentric) (Figs. 34-198 and 34-199). The mean wall thickness of 1.2 cm and

Figure 34-199. Actinomycosis infection involving the gastrointestinal tract. CT scan shows ill-defined soft tissue lesion (arrows) occupying the right lower abdomen as well as evidence of bowel wall thickening of the distal ileum (asterisks) and diffuse infiltration in the regional fat plane. (From Lee JJ, Ha HK, Park CM, et al: CT features of abdominopelvic actinomycosis involving the gastrointestinal tract. *Radiology* 220:76-80, 2001.)

the mean length of 8.3 cm overlap considerably with the parameters of other inflammatory bowel diseases. However, rather than bowel wall thickening, the most important CT feature for the correct diagnosis is the presence of a large mass adjacent to the involved bowel; we found that the mass was present in 17 of the 18 patients.³²¹ Such a mass appears to be predominantly cystic or solid.

The presence of abundant granulation and dense fibrous tissues in the solid components of these masses may cause hyperattenuation after infusion of contrast material. These lesions show an aggressive infiltration pattern with a propensity for crossing the fascial planes or boundaries and involve multiple compartments. These tendencies are attributed to the proteolytic enzyme produced by *A. israelii*. Soft tissue strandings are also prominent, surrounding the involved bowel or mass. Because of the size of the bacterium, the organism usually does not spread via the lymphatics; therefore, regional lymphadenopathy is uncommon or develops late.^{36, 612}

Early diagnosis is important to minimize morbidity and to avoid unnecessary surgery because the response to treatment with high doses of penicillin is usually favorable.^{39, 211}

Schistosoma Japonica Infection

Schistosoma japonica infection is confined to eastern Asia. Patients are infected by contact with fresh water that is infested with larvae. The schistosomal larvae penetrate the skin and pass via the systemic circulation to the portal vein and its tributaries. The eggs are the chief cause of tissue damage to the host. An intense granulomatous reaction is followed by irregular mucosal thickening, formation of granulomatous polyps, and, eventually, fibrosis. CT characteristically shows curvilinear or nodular calcification in the colon, appendix, or small bowel (Fig. 34-200).³²⁵ The calcified eggs are deposited more extensively in the submucosa and serosa.³²⁵

Vascular and Miscellaneous Conditions

Colonic Ischemia

Colonic ischemia is one of the most common vascular disorders of the large bowel in elderly people. Several forms of ischemic colopathy are recognized⁴⁹⁶:

Figure 34-200. *Schistosoma japonica* infection. CT scan shows diffuse colonic wall calcification (arrows) in the rectum and sigmoid colon. (Courtesy of T. Araki, M.D., Yamanashi University, Japan.)

- Reversible colopathy (submucosal or intramural hemorrhage)
- Transient colitis
- Chronic ulcerating colitis
- Stricture
- Gangrene
- Fulminant universal colitis

Acute ischemia results from an acute reduction in blood flow through an intestinal segment caused by an acute occlusive event or decreased splanchnic blood flow. A number of predisposing factors have been suggested, including arteriosclerotic heart disease, hypotensive episodes, cardiac and aortic surgery, myocardial infarction, digitalis treatment, arrhythmias, vasculitis, colonic obstruction, colonic infection such as CMV, and hypercoagulable states.

Although the common denominator producing ischemia in most of these circumstances is hypoxia, no specific cause of the ischemia is usually identified. Although any region of the colon is subject to focal ischemia,²⁹ the segments commonly affected by ischemic colitis are the junction between the superior and inferior mesenteric arteries near the splenic flexure (Griffith's point) and the anastomotic plexus between the inferior mesenteric artery and hypogastric vessels near the rectosigmoid region (critical point of Sudeck).

According to one report,⁵⁴⁶ isolated cecal ischemia may occur because the ileocecal region is also a "watershed area." The ischemic process tends to affect the mucosa initially; a severe and prolonged process causes involvement of only the muscularis propria. Mucosal damage is reversible, occurring as a self-limiting condition, whereas necrosis of the muscle layer can lead to the development of a fibrotic stricture or to necrosis with severe sepsis and perforation.

The diagnostic accuracy of CT in detection of colonic ischemia has not been well described in the literature, but improved contrast enhancement and scanning techniques may increase its sensitivity. On CT images, colonic ischemia appears as circumferential bowel wall thickening with or without a target sign, poor bowel wall enhancement, focal or diffuse bowel dilatation, mesenteric vascular thrombus, mesenteric vascular engorgement, pneumatosis intestinalis, portal or mesenteric venous gas, and pneumoperitoneum (Figs. 34-201 and 34-202).^{6, 146} Although similar CT findings can be seen in a variety of inflammatory conditions (e.g., ulcerative or granulomatous colitis, pseudomembranous colitis, or CMV colitis), the occurrence of segmental colonic involvement is much more often seen in colonic ischemia.²⁹

Differentiating reversible from irreversible ischemia may be important to establish the strategy of patient management. Except for the presence of portal air or intraperitoneal air, however, Balthazar and associates²⁹ observed that a single CT examination was limited in predicting the development of complications (stricture, infarction, perforation).

Radiation Colitis

Radiation colitis is generally observed in patients who receive abdominal and pelvic radiation with doses of 4500 to 6000 rads (45 to 60 Gy).⁵¹⁸ The latent period between

Figure 34-201. Colonic ischemia. CT scan shows heterogeneous colonic wall thickening (arrows) resulting from diffuse intramural hemorrhage or edema, which is confined to the right-sided colonic segment.

radiation therapy and the development of radiation damage is usually 6 to 24 months but can be longer than 30 years.¹¹⁸ Predisposing factors include diabetes, hypertension, atherosclerosis, prior abdominal surgery with adhesive bowel loops, and peritonitis before the radiation therapy.

Although the small intestine is more radiosensitive than the rectum, radiation injury occurs more commonly in the rectosigmoid because the rectum is fixed in position and in close proximity to many sites of malignancy, such as the cervix, uterus, ovary, bladder, and prostate. Depending on the area irradiated, other sites of the colon can be involved.

In contrast to the acute radiation changes in which viable regenerating cells within the crypts of the intestinal epithelium are damaged by the direct effects of the radiation, late radiation injury can cause bowel ischemia due to obliterative endarteritis in the fine intestinal vasculature of

Figure 34-203. Radiation colitis after radiation therapy for cervical cancer. CT scan shows bowel wall thickening (arrows) of the rectum and sigmoid colon with the "target sign."

the submucosa. Fewer than 2% of patients who receive radiotherapy ultimately require surgery resulting from perforation, bleeding, fistula, or stricture formation.⁶¹

CT may show bowel wall thickening and luminal narrowing of the irradiated bowel segment (Figs. 34-203 and 34-204). The thickened bowel wall commonly shows heterogeneous attenuation with target appearance. The perirectal changes include thickening of the perirectal fibrous tissue and increased perirectal fat, resulting in a widened presacral space.¹²⁹ Symmetrically proliferated fat immediately adjacent to the rectum and higher attenuation fibrous tissue surrounding it create a halo effect.¹²⁹ A fibrous connection between the sacrum and rectum may also be demonstrated. Because CT findings may closely simulate those of inflammatory bowel disease or colonic ischemia, correlation with the clinical history and radiation ports is necessary for a correct diagnosis.

MRI can also be used to evaluate suspected radiation

Figure 34-202. Colonic infarction. CT scan shows intramural gas (arrowheads) in the proximal transverse colon without well-defined bowel wall thickening. (From Ha HK. CT in the early detection of strangulation in intestinal obstruction. *Semin Ultrasound CT MRI* 16:141-150, 1995.)

Figure 34-204. Development of radiation colitis after radiation therapy for cecal lymphoma. CT scan shows bowel wall thickening (arrows) of the distal ileum, cecum, and ascending colon with marked and heterogeneous contrast enhancement. Pericolonic infiltration is minimal without free gas. Histopathologic examination of the resected specimen showed transmural infarction with microperforation.

Figure 34-205. Pneumatosis in the colonic wall caused by bowel infarction. CT scan shows diffuse intramural gas in the left-sided colon (asterisks).

colitis. According to a series by Sugimura and colleagues,⁵⁵⁹ the frequency of MRI tissue changes increased with incremental radiation doses. In addition to the perirectal changes seen on CT scans, MRI may have advantages in revealing the muscle and bone marrow changes in the region of the radiation port; the signal intensity of the affected muscle is increased on T2-weighted images and that of the marrow becomes increased on T1-weighted images.⁵⁵⁹

In differentiating between radiation-induced changes and residual recurrent tumor, MRI has a limited role, except for the presence of bulky mass that favors the diagnosis of recurrent tumor. In cases of infiltrative tumor growth in the rectum or bladder, differentiation is difficult.

Pneumatosis Intestinalis

Pneumatosis intestinalis (intramural gas) is characterized by the presence of gas in the wall of the GI tract. The disorder can be *primary* (15%) or *secondary* (85%).¹³³ Although the primary type is not associated with any known GI disease, the secondary form is related to various GI, pulmonary, and other conditions.¹³³

CT enables precise assessment of localization and extent of intramural gas accumulation (Fig. 34-205).²⁴⁴ Pneumatosis cystoides intestinalis has a benign course and is occasionally self-limited. In contrast, pneumatosis intestinalis is commonly associated with severe disease such as bowel infarction and is characterized by a linear and small cystic appearance of intramural gas.²⁴⁴ In addition, CT may allow for differentiation of primary and secondary forms and assessment of the prognosis.⁵²³ Pneumatosis intestinalis may be occasionally overlooked as intraluminal gas; therefore, the use of lung window settings is necessary in equivocal cases.

Hepatic Mass Lesions

Jeffrey D. McTavish, Pablo R. Ros

Hepatic masses can be classified in the following categories: (1) primary benign neoplasms, (2) primary malignant neoplasms, (3) secondary malignant liver neoplasms, and (4) infectious lesions.

Primary hepatic neoplasms may arise from each one of the cellular components of the liver: hepatocytes, biliary epithelium, and mesenchymal tissues, which explains the varied gamut of liver tumors.⁴⁹ This chapter reviews primary benign and malignant liver lesions, then secondary malignant neoplasms and infectious lesions. We complete the chapter with our practical approach to the differential diagnosis of liver masses.

Computed tomography (CT) has assumed a primary role in the evaluation of hepatic masses. Magnetic resonance imaging (MRI) is often used to further characterize a mass found by CT or ultrasound and may be helpful in formulating a more specific differential diagnosis. The development of tissue-specific contrast agents for use in MRI holds promise for increased sensitivity and specificity.

Benign Liver Neoplasms

Hemangioma

The hemangioma, a benign tumor, is composed microscopically of multiple vascular channels lined by a single layer of endothelial cells that are supported by thin septa of fibrous stroma. Hemangiomas are grossly solitary, well circumscribed, and blood-filled, ranging in size from a few millimeters to larger than 20 cm.⁴⁹ Although early reports described them as a solitary lesions in 90% of cases, with the increased use of imaging there is mounting evidence that the number of multiple hemangiomas is higher than 10% and probably above 30%. By convention, *giant hemangiomas* are larger than 10 cm. On cut sections, areas of fibrosis are almost always present, with cystic zones and areas of necrosis often, but less frequently, seen.^{123, 216}

The hemangioma is the most common benign liver tumor seen at imaging, with an incidence ranging from 0.4% to 20%, the higher figure coming from a prospective autopsy series that involved a dedicated search for this tumor.¹²³ Hemangiomas occur primarily in women and may be present at any age. Most hemangiomas are clinically silent, because of their small size, but may become symptomatic when enlarged or when they compress adjacent structures, only then becoming a surgical lesion primarily to relieve pain. The remote chance of rupture does not usually constitute an indication for surgery.

On unenhanced CT scans, hemangiomas appear as low-attenuation masses with lobulated, well-defined borders. Calcification may be present in up to 20% of cases, either

amorphous or in the form of phleboliths.²¹³ Following intravenous (IV) contrast administration, large feeding vessels cause peripheral globular enhancement with centripetal fill-in of the lesion within 15 minutes (Figs. 35-1A-D and 35-2A-D).^{76, 77} Unfortunately, some metastases can also have peripheral globular enhancement.

A study by Leslie and coauthors¹⁴⁰ found that 8% of metastases had peripheral globular enhancement. In this study, all of the metastases had enhancement that was hypointense to the aorta, whereas the enhancement in hemangiomas was isointense or hyperintense to the aorta. Although small (<2 cm) lesions may show complete enhancement, the large tumors may have central nonenhancing zones that result from fibrosis and hemorrhage.²²⁶ The centripetal enhancement may be demonstrated by dynamic scanning through the liver at 30-second intervals for the first few minutes, potentially followed by longer intervals up until 20 minutes if the lesion does not completely opacify. Centripetal filling alone is not a characteristic sign of hemangioma because all benign and malignant liver tumors, except for *focal nodular hyperplasia* (FNH), may have peripheral vascular supply and thus enhancement. To diagnose a hemangioma by CT, a lesion must fulfill the diagnostic triad of enhancement, which is equal or hyperintense to the aorta, which persists on delayed imaging, and appears in a peripheral globular fashion. However, this technique has been largely replaced by the increased specificity of MRI with IV contrast in the evaluation of a suspected hemangioma.^{97, 282}

MR imaging is used to evaluate suspected hemangiomas because of the tumor's characteristic appearance resulting from slow blood flow through the vascular channels of the lesion. On *T1-weighted* (T1W) images, hemangiomas are hypointense to the surrounding hepatic parenchyma with smooth, well-defined, often lobulated margins (Fig. 35-3A and B). On *T2-weighted* (T2W) images, they become significantly hyperintense to normal liver, increasing in relative signal intensity to the liver with increasing echo time (TE).^{111, 112, 237}

Spin-echo pulse sequences with a repetition time (TR) of 2000 msec, with an increasing TE from 60 to 180 msec, are often used. Unfortunately, some malignant lesions, particularly hypervascular metastases, can also have quite long T2 values and can mimic hemangiomas on T2-weighted images. A prospective study¹⁴⁵ found that 39% of endocrine tumor metastases could not be distinguished from hemangiomas by T2 appearance. Thus, the diagnosis of hemangioma by MRI rests not only in the signal characteristics but also in morphologic features (e.g., sharp and geographic margins, lack of peripheral halo in T2-weighted images, and enhancement pattern).

Dynamic gradient-echo MR imaging, after IV injection

Figure 35-1. Hemangioma. A–D, a Large lesion in the right hepatic lobe after intravenous gadolinium (Gd-DTPA) administration. The lesion enhances in a peripheral, globular fashion and gradually fills in.

of an intravascular contrast agent, such as gadolinium-diethylenetriamine-pentaacetic acid (Gd-DTPA), is useful in increasing the specificity of MRI for the study of hemangiomas.^{97, 282} Fast T1-weighted, gradient-echo images, such as fast low-angle shot (FLASH) or spoiled gradient-recalled acquisition in the steady state (SPGR, or spoiled GRASS), are obtained before contrast, which are repeated at approximately 30-second intervals following contrast injection (0.05 mmol/kg). With current technology, most of the liver can be scanned using this technique, obviating the need for “single-level” scanning.

Peripheral globular enhancement with centripetal fill-in, similar to that demonstrated by CT, is observed. Central areas lacking enhancement, especially in large tumors, correspond to areas of fibrosis that appear as low attenuation on CT.⁴⁰ These fibrotic areas appear hypointense on T2-weighted images, which may aid the imager in distinguishing a large heterogeneous hemangioma (containing areas of fibrosis) from a necrotic malignancy in which the necrotic areas are hyperintense on T2-weighted images. After administration of ultra-small superparamagnetic iron oxide (USPIO), hemangiomas demonstrate signal loss because their slowly flowing vascular spaces represent blood pool (Fig. 35-4).

Focal Nodular Hyperplasia

FNH is a benign tumor-like condition characterized by a central fibrous scar surrounded by nodules of hyperplastic hepatocytes and small bile ductules.⁴⁹ Vessels are prominent throughout the lesion but are most abundant in the fibrous scar. FNH is believed to be a hyperplastic response to an underlying arteriovenous malformation (AVM).²⁶⁶

FNH is well circumscribed, usually solitary (95%), is often present on the liver surface, and may be pedunculated. Although FNH is sharply marginated, there is no capsule. Most lesions are smaller than 5 cm, with a mean diameter of 3 cm at discovery. Occasionally, FNH may replace an entire lobe of the liver (*lobar FNH*).⁴⁹

FNH is the second most common benign tumor of the liver seen at imaging, representing 8% of primary hepatic tumors.⁴⁹ It is more prevalent in women and has been associated with oral contraceptive use, although not as often as with hepatocellular adenoma.⁴¹ It is usually discovered in the third to fifth decades of life as an incidental finding during imaging, surgery, or autopsy; fewer than one third of cases (usually large lesions) are discovered because of clinical symptoms, such as epigastric pain and right upper quadrant pain.

Figure 35-2. Multiphase enhancement of a hemangioma. *A*, Arterial phase, enhancing mass in the right hepatic lobe. *B*, Parenchymal phase. Progressive enhancement is seen. Note enhancement of portal veins without hepatic venous opacification. *C*, Hepatic venous phase. All of the hepatic vessels are enhanced. Parenchymal enhancement is maximal during this phase. *D*, An intrahepatic mass and the hepatic vessels are demonstrated on this 3D image.

On unenhanced CT scans, FNH appears as a homogeneous, low-attenuation mass, often with a central low-density area representing the central scar. After IV contrast injection, the tumor becomes isodense to slightly hyperdense to normal liver while low attenuation of the central scar may remain.^{156, 273} If a low-density central scar is not

present, the tumor may be quite subtle, producing a bulge or deformity of the liver if it is only peripherally located.²¹⁹ On delayed images, contrast medium accumulates within the scar. This sign has been described as highly indicative of FNH.¹⁵⁶

On unenhanced T1-weighted MR images, FNH is typi-

Figure 35-3. Hemangioma. A, Unenhanced T1-weighted image demonstrates a large lesion in the right hepatic lobe with low signal intensity. B, Unenhanced T2-weighted image demonstrates very high signal intensity, or a “light bulb” appearance.

cally isointense to liver, becoming isointense to slightly hyperintense on T2-weighted images. The central scar, when apparent, is usually hypointense on T1-weighted images and hyperintense on T2-weighted images (Fig. 35-5).^{139, 162, 221, 260} Unenhanced MR imaging has 70% sensitivity and 98% specificity in the diagnosis of FNH.³⁷ Following injection of an extracellular contrast agent (e.g., Gd-DTPA, Gd-DOTA), there is a high degree of enhancement during the early arterial phase^{153, 158}; further, there is often delayed enhancement of the central scar owing to its excellent vascularity.^{158, 251}

SPIO particles are coated crystalline iron oxide particles, which are taken up by the reticuloendothelial system. In a magnetic field, these particles become strongly magnetized, a phenomenon termed *magnetic susceptibility*. SPIO particles create magnetic field inhomogeneity, which promotes dephasing of protons and results in T2 signal loss. SPIO particles are phagocytosed by FNH because they contain

Kupffer cells and have an excellent vascular supply. Studies have demonstrated significant uptake of SPIO by FNH^{92, 200, 206}; however, the relative signal intensity of an FNH after administration of SPIO varies. In one study, most FNHs lost less signal than liver parenchyma (which, on average, loses 74% to 78% of its signal after SPIO^{165, 200}), some lost more signal than liver, and some FNHs lost no signal (Fig. 35-6).⁹² After SPIO administration, FNH may also lose signal (Fig. 35-7).

Because FNHs contain hepatocytes, they often take up hepatobiliary agents as well (e.g., Gd-EOB-DTPA), appearing hyperintense to liver parenchyma.²⁶¹

Hepatocellular Adenoma

Hepatocellular adenoma (HCA), a benign lesion, consists of hepatocytes arranged in cords that occasionally

Figure 35-4. Hemangioma. A, Unenhanced T2-weighted image demonstrates a 4-cm lesion in the right hepatic lobe. B, T2-weighted image after ultra-small superparamagnetic iron oxide (USPIO) administration demonstrates signal loss, reflecting blood pool effects.

Figure 35-5. Focal nodular hyperplasia. *A*, Unenhanced T1-weighted image demonstrates an exophytic lesion, extending from the right hepatic lobe, that is isointense to hepatic parenchyma. *B*, Unenhanced T2-weighted image demonstrates the lesion to be isointense to hepatic parenchyma. *C-F*, T1-weighted images after gadolinium (Gd-DTPA) administration demonstrate early arterial phase enhancement with rapid washout. The central scar is hypoattenuating during the arterial phase and enhances in the later phases.

Figure 35-6. Focal nodular hyperplasia. *A*, Unenhanced T1-weighted image demonstrates a 2-cm lesion in the right hepatic lobe. *B*, T2-weighted image after superparamagnetic iron oxide (SPIO) enhancement demonstrates signal loss of the lesion. *C*, Signal loss is seen in a different patient between unenhanced T2-weighted images. *D*, SPIO-enhanced imaging.

Figure 35-7. Focal nodular hyperplasia. *A*, Unenhanced T2-weighted image demonstrates a large lesion in the right hepatic lobe. *B*, T2-weighted image after superparamagnetic iron oxide (USPIO) administration demonstrates signal loss.

form bile.⁴⁹ Although known to contain Kupffer cells, this tumor lacks portal tracts, hepatic veins, and biliary canaliculi.⁸⁹ Fat and glycogen-rich hepatocytes are often present.

Grossly, hepatocellular adenoma is usually single, 8 to 10 cm in diameter at discovery, with pedunculation present in 10% of cases.⁴⁹ A capsule containing large vessels is often present. On cut section, the tumor often contains areas of hemorrhage or infarction, with internal hemorrhage one of its hallmarks. Rupture of an adenoma may result in hemoperitoneum. In rare instances, multiple adenomas may be seen, usually involving both hepatic lobes; this situation is called *multiple hepatocellular adenomatosis*.^{36, 150} Multiple hepatocellular adenomas have been associated with type 1 glycogen storage disease.⁴⁴

Most cases of HCA are found in women of childbearing age who have used oral contraceptives; the estimated overall incidence is 4 per year per 100,000 users,^{41, 210} which declines to 1 per million in women who have not used oral contraceptives in the preceding 2 years. When the tumor is large, upper abdominal pain may lead its discovery.

Although benign, this tumor is considered surgical because of its potential for rupture. On unenhanced CT scans, HCA appears as a low-attenuation mass because of the fat

and glycogen contained within the tumor.^{156, 273} Areas of increased attenuation that correlate with fresh hemorrhage may be seen, creating a heterogeneous appearance. After IV contrast administration, enhancement of the peripheral vessels occurs early with a centripetal enhancement pattern somewhat similar to hemangioma (see Figs. 35–5A and 35–9A).¹⁵⁶ Unlike the case of hemangioma, however, contrast enhancement does not persist in later phases because of arteriovenous shunting present within the HCA.²¹³

On T1-weighted MR images, areas of mildly increased signal intensity may be demonstrated because of the presence of fat and hemorrhage associated with this lesion (Figs. 35–8 and 35–9B).^{81, 173, 185, 212, 221} The appearance on T2-weighted images is often heterogeneous, with hypointense, isointense, and hyperintense areas, depending on the nature of the lesion and the stage of hemorrhage (Fig. 35–9C). The heterogeneous appearance on both T1-weighted and T2-weighted images makes it difficult to distinguish from hepatocellular carcinoma. A capsule often appears as a hypointense rim surrounding the tumor and may contain large vessels.^{81, 212}

SPIO uptake is common in these lesions,^{92, 200} depending on the variable presence of reticuloendothelial cells (Fig.

Figure 35–8. Hepatocellular adenoma in a 29-year-old woman. A, Contrast-enhanced CT scan demonstrates a large mass of mixed attenuation in the right hepatic lobe. B, T1-weighted image (TR = 450 msec, TE = 15 msec) shows the mass to have slightly increased signal intensity relative to the liver. C, Fat-suppression T1-weighted image (TR = 550 msec, TE = 15 msec) now shows the lesion to be lower in signal intensity relative to the liver. This indicates that the mass has a fatty composition. D, T2-weighted image (TR = 2000 msec, TE = 90 msec) shows the mass to be slightly hyperintense relative to the liver.

Figure 35-9. Hepatocellular adenoma in a 25-year-old woman. **A**, Contrast-enhanced CT scan demonstrates a large mass in the upper abdomen (**M**). **B**, Coronal T1-weighted image (TR = 450 msec, TE = 15 msec) shows the pedunculated mass to involve the inferior margin of the liver. Areas of hyperintensity (arrows) are related to recent hemorrhage. **C**, T2-weighted image (TR = 2000 msec, TE = 15 msec) demonstrates very heterogeneous signal intensity caused by hemorrhage at various stages.

35-10). In their series, Grandin and coworkers⁹² found that adenomas had similar signal loss to that of FNH. These lesions take up hepatobiliary contrast agents (e.g., manganese-DPDP, Gd-EOB-DTPA)⁹⁸ as a result of the presence of functioning hepatocytes.

Nodular Regenerative Hyperplasia

Nodular regenerative hyperplasia (NRH) of the liver is defined as the presence of diffuse, multiple regenerative nodules not associated with fibrosis.²⁴¹ The nodules consist of cells that resemble normal hepatocytes. The absence of fibrosis is an important distinction between NRH and regenerating nodules of cirrhosis.²⁴⁵ Multiple diffuse, bulging nodules are present on the liver surface and vary in size from a few millimeters to several centimeters in diameter.

NRH (also called nodular transformation of the liver, diffuse nodular hyperplasia, and noncirrhotic nodulation),⁴⁹ is a rare condition that is discovered incidentally or during the evaluation of portal hypertension. Several drugs (e.g., steroids and antineoplastic medications) as well as multiple systemic conditions (e.g., myeloproliferative, lymphoprolif-

erative, immunologic, and collagen vascular disorders) have been associated with NRH.^{52, 180, 245, 267} It is the leading cause of noncirrhotic portal hypertension in the Western Hemisphere. Complications include esophageal varices and ascites.¹⁷⁰

The CT appearance of NRH may range from that of a normal liver to that of focal liver nodules of varied but predominantly low attenuation.⁵² Hemorrhage may occur, resulting in a complex mass of mixed density. Descriptions in the literature regarding the MRI appearance of NRH are limited. Casillas and colleagues described the appearance in five patients, which was subtly hypointense or hyperintense before contrast administration. Enhancement was similar to that of normal hepatic parenchyma.³²

Adenomatous Hyperplastic Nodule

Adenomatous hyperplastic nodule (AHN), also referred to as *adenomatoid hyperplasia* or *regenerative nodule*, is a benign but premalignant lesion that appears in cirrhotic livers. When larger than other regenerative nodules of the cirrhotic liver, it has been called a *macroregenerative nodule*. Histologically, it contains portal tracts and bile ducts but has no capsule.⁴⁹

Figure 35-10. Hepatocellular adenoma. A, Unenhanced T2-weighted image demonstrates a very large hepatic lesion. B, T2-weighted image after superparamagnetic iron oxide (SPIO) enhancement demonstrates signal loss from the lesion.

Unenhanced CT scans show a low-attenuation nodule that is indistinguishable from a small hepatocellular carcinoma (HCC). CT arterial portography (CTAP) is useful because an AHN is not apparent (because of its portal blood flow), whereas HCC is seen as a hypoattenuating lesion (because of a lack of portal flow).¹⁶¹ CTAP, however, is seldom used as a result of its invasive nature.

MRI is also useful for distinguishing AHN from HCC.¹⁶⁰ On T1-weighted images, AHN is frequently hyperintense, whereas T2-weighted images demonstrate a hypointense nodule (Fig. 35-11).^{110, 160, 188} This is in contrast to HCC, which is often hyperintense on T2-weighted images. The finding of a “nodule within a nodule” on gradient-echo and T2-weighted images, consisting of a large, low-intensity nodule containing a smaller nodule of isointensity or

hyperintensity relative to liver, suggests the development of a small HCC within a hyperplastic nodule.¹⁶⁷ After injection of an extracellular contrast agent, an AHN typically does not enhance to a greater degree than liver parenchyma, thus further differentiating it from HCC.¹⁷⁸

Lipomatous Tumors

In rare cases, benign hepatic tumors consisting of fat cells may be seen. These include lipoma, hibernoma, and mixed tumors such as angiomyolipomas (fat and blood vessels), myelolipoma (fat and hematopoietic tissue), and angiomyolipoma (fat, blood vessels, and hematopoietic tissue).⁸⁷ Hepatic lipomatous tumors usually are round, well-

Figure 35-11. Adenomatous hyperplastic nodules in a man with hepatocellular carcinoma. A, T1-weighted image (TR = 300 msec, TE = 15 msec) shows a small hyperintense nodule of the left hepatic lobe (arrow) and a larger hyperintense nodule of the right hepatic lobe (arrowhead). B, T2-weighted image (TR = 2000 msec, TE = 90 msec) demonstrates the adenomatous hyperplastic nodule of the left hepatic lobe to be of low signal intensity whereas the hepatocellular carcinoma of the right hepatic lobe is of high signal intensity.

Figure 35-12. Tuberous sclerosis in a woman with angiomyolipomas of the liver and kidneys.

A, Contrast-enhanced CT scan demonstrates multiple lipomatous lesions of the liver having fat attenuation. A large pedunculated angiomyolipoma (*arrow*) is present in the lateral segment of the left hepatic lobe.

B, T1-weighted image (TR = 300 msec, TE = 15 msec) demonstrates the multiple lipomatous tumors of the liver to be of increased signal intensity similar to that of the subcutaneous and retroperitoneal fat. Fibrous septa of the angiomyolipoma of the left hepatic lobe have low signal intensity.

C, T2-weighted image (TR = 2400 msec, TE = 90 msec) shows the lesions to continue to have signal intensity similar to that of other fatty areas.

D, Fat-suppression T1-weighted image (TR 800 msec, TE = 15 msec) demonstrates the fatty lesions to be of low signal intensity similar to that of other fatty areas.

E, Fat-suppression T1-weighted image (TR = 800 msec, TE = 15 msec) obtained after intravenous gadolinium (Gd-DTPA) demonstrates mild enhancement of the septa (*arrows*) of the angiomyolipoma of the left hepatic lobe, similar to that seen on CT.

defined, solitary lesions that occur in a noncirrhotic liver.⁸⁸ Their microscopic appearance is similar to that seen in lipomatous lesions of soft tissues.⁴⁹

Hepatic lipomatous tumors may occur in approximately 10% of patients with tuberous sclerosis and renal angioliomas (Fig. 35-12),²⁰⁸ although solitary liver lipomas may be present without other lesions (Fig. 35-13). Most are found incidentally and are asymptomatic; occasionally, however, they may hemorrhage, causing abdominal pain.

Benign lipomatous tumors of the liver have the characteristic CT appearance of a lesion with fat attenuation (see Figs. 35-12 and 35-13).^{22, 208} In a reported case of the MRI findings of a hepatic lipoma, the lesion appeared homogeneous and well defined, with similar signal intensity to retroperitoneal fat on all pulse sequences (Fig. 35-13B).²²

Infantile Hemangioendothelioma

Infantile hemangioendothelioma (IHE) is a benign vascular tumor consisting of vascular channels formed by proliferating endothelial cells. Although usually presenting as multiple spongy nodules that vary in diameter from a few millimeters to 15 cm or more, a solitary lesion is a less common variant.¹⁶³ Nodules may become fibrotic with age.²¹⁹

Microscopically, IHE consists of a proliferation of vascular channels with an endothelial cell lining. Areas of hemorrhage, thrombosis, fibrosis, and calcification are common. Cavernous areas are also seen.⁴⁹

IHEs are the most common liver tumor during the first 6 months of life; 90% of them are discovered during that period. IHE accounts for 12% of all childhood hepatic tumors, with girls being affected more often than boys.⁵⁶ Hepatomegaly, congestive heart failure (up to 25% of cases), thrombocytopenia (due to trapping of platelets by the tumor), and occasional rupture with hemoperitoneum

may be seen.^{26, 141} Cutaneous hemangiomas may be associated with the multinodular form of IHE (in up to 40% of patients) and may involve other organs.⁴⁹ Although IHE may enlarge with resulting hemodynamic compromise, spontaneous involution occurs with time if the child survives.¹⁹⁵

On CT scans, IHE demonstrates an appearance similar to that of hemangioma.¹⁴⁹ On precontrast scans, it appears as a well-defined mass that may contain calcifications (Fig. 35-14A). After IV contrast administration, peripheral enhancement occurs (Fig. 35-14B). On delayed CT scans, a variable degree of centripetal enhancement is seen with prolonged and persistent contrast enhancement, similar to that seen with hemangioma.¹²⁶

MR images of IHE demonstrate a heterogeneous appearance on both T1-weighted and T2-weighted images because of the presence of hemorrhage, necrosis, and fibrosis (Fig. 35-15). The vascular nature of the lesion produces various degrees of hyperintensity on T2-weighted images, similar to the hyperintensity of a hemangioma.¹²⁶

Mesenchymal Hamartoma

Mesenchymal hamartoma is a benign cystic developmental lesion consisting of gelatinous mesenchymal tissue with cyst formation and remnants of normal hepatic parenchyma.^{55, 244} It is large, usually 15 cm or more in diameter at diagnosis, with cysts present in 80% of cases.¹⁰⁶ It is a well-defined tumor that may be encapsulated or pedunculated.²¹⁵ On cut section, this tumor may have either mesenchymal predominance (a solid appearance) or cystic predominance (multiloculated cystic masses). Microscopically, it consists of cysts, remnants of portal triads, hepatocytes, and fluid-filled mesenchyme.

Mesenchymal hamartoma is uncommon and accounts for only 8% of all childhood liver masses.¹⁰⁶ Most cases are discovered by the time the child is 3 years of age, and

Figure 35-13. Lipoma of the liver. A, Contrast-enhanced CT scan demonstrates a lesion of low attenuation (arrow), with similar attenuation to subcutaneous and retroperitoneal fat. B, T1-weighted image demonstrates the lesion's high signal intensity, similar to that of other fatty areas. (From Marti-Bonmati L, Menor F, Vizcaino J, et al: Lipoma of the liver: US, CT and MRI appearance. *Gastrointest Radiol* 14:155-157, 1989.)

Figure 35-14. Infantile hemangioendothelioma in a 1-month-old boy. *A*, Unenhanced CT scan shows a large mass of the liver containing calcifications (*arrows*). *B*, Contrast-enhanced CT scan shows the enhancement beginning in the periphery, similar to that seen with hemangioma.

Figure 35-15. Infantile hemangioendothelioma in an infant girl. *A*, T1-weighted image, obtained with the patient in the decubitus position, reveals a large, multinodular hepatic lesion of heterogeneous signal intensity that fills the abdomen. *B*, T2-weighted image shows that the lesion has predominantly high signal intensity because of its vascular nature.

there is a slight male predominance.²⁴⁴ Although slow, progressive, and painless abdominal enlargement is seen, occasionally sudden enlargement may result from rapid fluid accumulation in the cysts. Mass effect from the bulky tumor may cause respiratory distress and lower extremity edema.²⁴⁷ Extensive surgery is not necessary because mesenchymal hamartoma is not a neoplasm but a failure of normal development; thus, simple excision, marsupialization, or incisional drainage may be all that is required for treatment.²¹⁵

On CT scans, mesenchymal hamartoma appears as a well-defined mass with central areas of low density and internal septa (Fig. 35-16A). Both solid and cystic areas are seen.^{215, 236}

The MRI appearance of mesenchymal hamartomas depends on their mesenchymal (stromal) or cystic predominance. Lesions of mesenchymal predominance have lower intensity than normal liver on T1-weighted images because of their fibrotic tissue content. Cystic-predominant lesions are of variable intensity on T1-weighted images and are significantly hyperintense on T2-weighted images because of the cyst's contents (see Fig. 35-16B and C). Multiple septa are best seen on T2-weighted images, which demonstrates the complex nature of the cystic mass.¹⁹⁰

Simple Hepatic Cysts

A simple hepatic cyst, or *bile duct cyst*, is defined as a solitary, unilocular cyst with a lining composed of a single layer of cuboidal bile duct epithelium.⁴⁹ Its wall is a thin (<1 mm thick) layer of fibrous tissue, surrounded by normal hepatic parenchyma. Although the simple hepatic cyst is thought to be of congenital, developmental origin, usually it is discovered in adults.¹⁴⁷

The incidence of simple hepatic cysts ranges from 1% to 14% in autopsy series. These cysts tend to occur more frequently in women than in men by a 5:1 ratio.⁴⁹ They are usually found incidentally but may cause mass effect, resulting in abdominal pain or jaundice.²²³ If the cyst is symptomatic, surgical excision or percutaneous aspiration with alcohol sclerotherapy may be helpful.^{11, 119, 147, 223}

On CT scans, a simple hepatic cyst appears as a well-defined intrahepatic mass having water attenuation, a round or oval shape, smooth thin walls, no internal structure, and no enhancement after IV contrast administration.^{9, 179} Usually solitary and peripheral, the cysts may be multiple and occur more centrally. When more than 10 cysts are present, the diagnosis of polycystic disease should be considered.²⁴ Cysts that become complicated by hemorrhage

Figure 35-16. Mesenchymal hamartoma in a 14-month-old boy. A, Contrast-enhanced CT scan shows a large cystic mass of the liver with several locules of fluid separated by septa. B, Coronal T1-weighted image (TR = 450 msec, TE = 15 msec) shows the predominantly cystic mass to be composed of slightly hyperintense proteinaceous fluid with locules of lower-intensity fluid. C, T2-weighted image (TR = 2000 msec, TE = 90 msec) demonstrates the hyperintense mass to contain several low-signal-intensity septations that surround locules of lower-intensity fluid.

or infection may have septations and internal debris as well as wall enhancement.

MRI of simple hepatic cysts demonstrates hypointensity on T1-weighted images and hyperintensity on T2-weighted images.²⁷⁸ It is difficult to differentiate a cyst from a hemangioma without the use of IV contrast agents.

Congenital Hepatic Fibrosis and Polycystic Liver Disease

Congenital hepatic fibrosis and polycystic liver disease are part of the spectrum of *fibropolycystic disease* of the liver. Congenital hepatic fibrosis is characterized by periductal fibrosis and aberrant bile duct proliferation.⁴⁹ Typically, the cysts are visible only with magnification. However, numerous large and small cysts, which are identical on pathologic examination to simple or bile duct cysts, are present with fibrosis in the polycystic liver disease variant.

In the patient with polycystic liver and/or kidney disease, hepatic tissue surrounding the cysts is not normal and commonly contains von Meyenburg's complexes and increased fibrous tissue. Hepatic involvement occurs in approximately 30% to 40% of patients with autosomal dominant (adult) polycystic kidney disease.¹¹⁹ Occasionally, hepatic cysts occur without radiologically evident renal cysts; approximately 70% of patients with polycystic liver disease also have autosomal dominant polycystic kidney disease.²⁴

Most patients with congenital hepatic fibrosis present in childhood with complications of portal hypertension, such as bleeding varices.¹²⁵ In patients with polycystic disease, lesions are often found incidentally on imaging studies.

CT demonstrates multiple cysts of the liver and may reveal calcification of the cyst walls (Figs. 35-17 and 35-18A). Hemorrhage into cysts may occur, as in the kidneys, and results in increased attenuation of the cystic contents.^{24, 142, 179} Contrast enhancement of a cyst should not occur unless the cyst becomes infected.

MRI demonstrates simple, noncomplicated cysts as hav-

ing decreased signal intensity on T1-weighted images and increased signal intensity on T2-weighted images (Fig. 35-18B and C). Calcifications of cyst walls appear as areas of signal void, although detection may be difficult. When hemorrhage occurs, variations in signal intensity on all pulse sequences may be seen.²⁷⁵

Malignant Hepatic Tumors Hepatocellular Carcinoma

The most common primary malignant hepatic tumor and one of the most prevalent malignancies in the world, HCC is characterized by malignant hepatic cells that mimic normal hepatocytes.⁴⁹ On microscopic examination, it is often difficult to distinguish the cells of HCC from normal hepatocytes or hepatocellular adenoma; this problem affects the accuracy of cytologic needle aspiration biopsy.¹⁸⁴ The malignant hepatocytes may be so well differentiated in some tumors as to even produce bile, which is found in the tumor cells and in biliary canaliculi. Fat and glycogen are often present in the cytoplasm of HCC hepatocytes.

Several growth patterns occur. The most common is the *trabecular* pattern, which may give the tumor a pseudoglandular or acinar appearance. When the trabeculae grow together, a *solid* pattern is produced.

Grossly, three major patterns of growth are seen: (1) a large solitary mass, (2) nodular or multifocal masses, and (3) diffuse or cirrhotomimetic HCC. A variant of the solitary form, encapsulated HCC, may carry an improved prognosis because of easier resectability.^{75, 217} In all forms of growth, HCC is a soft tumor with frequent necrosis and hemorrhage as a result of its lack of stroma. Vascular invasion of portal and hepatic veins is common, although biliary invasion is uncommon.²⁴⁶

The incidence of HCC is highest in sub-Saharan Africa and Asia, with its peak incidence in Japan.^{176, 181} In the high-incidence areas, presentation is often at a young age (30 to 45 years). Men are affected eight times more frequently than women. The primary etiologic factors in these areas are hepatitis B virus and aflatoxin exposure. HCC is aggressive in these patients and may present with both rupture of the liver and hemoperitoneum.

In the Western Hemisphere, where HCC occurs at a lower rate, the usual age of presentation is 70 to 80 years, with a male-to-female ratio of 2.5:1.¹⁷⁶ Most patients have underlying cirrhosis caused by alcohol abuse, hemochromatosis, or toxin exposure, with hepatitis B virus increasingly becoming the responsible agent, especially in younger patients. Symptoms are insidious in onset and include malaise, fever, and abdominal pain. Jaundice is rare, and liver function test results may be normal except for an elevated α -fetoprotein level. Paraneoplastic syndromes may occur, including erythrocytosis, hypercalcemia, hypoglycemia, hypercholesterolemia, and hirsutism.

Unenhanced CT scans usually demonstrate HCC as a large, hypodense mass, often with central areas of low attenuation representing areas of necrosis. On unenhanced CT scans, the tumor is occasionally isodense to the liver.^{134, 249} Calcification is rarely present.^{133, 247} In North American and European patients, associated cirrhosis (60%) or hemochromatosis (20%) is often present (Fig. 35-19).⁷⁵ After

Figure 35-17. Polycystic kidney and liver disease in a 60-year-old woman. Noncontrast CT scan demonstrates multiple cysts of varying attenuation involving the liver. A few calcifications (arrows) of the cyst walls are present.

Figure 35-18. Polycystic kidney and liver disease in a 48-year-old woman. *A*, Noncontrast CT scan shows multiple cysts involving the liver and both kidneys. Several calcifications are demonstrated. *B*, T1-weighted image (TR = 450 msec, TE = 15 msec) shows multiple low-signal-intensity cysts of both the liver and kidneys. Several cysts demonstrate high-signal intensity, which corresponds to hemorrhage (arrows). *C*, T2-weighted image (TR = 2500 msec, TE = 90 msec) shows the cysts with varying degrees of hyperintensity. Areas of signal void that correspond to calcifications are better visualized (arrows).

Figure 35-19. Hemochromatosis with multifocal hepatocellular carcinoma. Unenhanced CT scan demonstrates multiple masses of low attenuation relative to the overall increased density of the liver as a result of the high levels of iron in the liver. The lesion of the posterior segment of the right hepatic lobe has portal vein invasion, which causes the venous dilatation peripheral to the lesion.

Figure 35-20. Hepatocellular carcinoma in a 70-year-old man with a cirrhotic liver. Contrast-enhanced CT scan demonstrates a predominantly low-attenuation mass with enhancement of the non-necrotic area of the tumor (straight arrow). An enhancing vessel (curved arrow) is well demonstrated on this dynamic bolus-enhanced scan. A rim of ascites is present.

IV contrast administration, the non-necrotic areas of the tumor may enhance and appear hyperdense (Fig. 35-20).⁷⁵ If a capsule is present, it appears as an enhancing rim around the tumor (Fig. 35-21).²¹⁷

In the *solid* histologic forms of HCC, the postcontrast attenuation of the lesion may be similar to that of the surrounding liver; in these instances, lesion detection relies on a change in liver contour. Low attenuation persists in areas of necrosis and fat.^{134, 283} Vascular invasion of venous structures, including the portal veins, hepatic veins, and inferior vena cava, may be seen after contrast administration (Fig. 35-22).^{157, 169, 246} CTAP, CT after iodized oil (Lipiodol) injection, and intraoperative ultrasound are more sensitive than IV bolus dynamic CT in detecting HCCs smaller than 3 cm.²⁴⁸ However, contrast-enhanced CT is more accurate than abdominal sonography for identifying and staging HCC.¹⁶⁹ Intraperitoneal rupture of HCC may be demonstrated by CT as high-density blood adjacent to a peripheral mass, and its occurrence may be predicted in patients with very large peripheral tumors with extrahepatic protrusion (Fig. 35-23).¹²²

MR images of HCC reveal a variable appearance on T1-weighted images, depending on the degree of fatty

change, internal fibrosis, hemorrhage, and dominant histologic pattern (Fig. 35-24C; see Fig. 35-22A).^{58, 114, 221} T2-weighted images usually show HCC as hyperintense relative to the liver, with higher intensity seen in areas of necrosis (Fig. 35-25; see Figs. 35-22D and 35-24B). A low-signal-intensity rim on T1-weighted images, which represents the tumor capsule, may be seen. This capsule appears on T2-weighted images as a double layer of inner low signal and outer high signal in approximately 50% of encapsulated HCCs; the inner layer represents fibrous tissue and the outer layer consists of compressed vessels and bile ducts.¹¹⁴

Gradient-echo MRI and other flow techniques are sensitive in detecting hepatic and perihepatic vascular invasion.¹⁸⁷ As with CT, local staging of HCC may be aided by multiplanar imaging or three-dimensional (3D) reconstruction. Contrast-enhanced MRI of HCC reveals variable enhancement of the lesion after IV gadolinium administration as a result of the tumor's hypervascular nature.^{189, 282} Intravenous SPIO increases the sensitivity in the detection of HCC, even in the setting of cirrhosis,²⁸¹ by decreasing the signal intensity of normal parenchyma (see Fig. 35-25).⁶⁷ Well-differentiated HCC has been reported to take

Figure 35-21. Encapsulated hepatocellular carcinoma in a cirrhotic liver. A, Contrast-enhanced CT scan demonstrates the well-defined, low-attenuation mass, which deforms the liver contour. B, CT scan performed during hepatic arterial injection of contrast more accurately demonstrates the enhancing rim.

Figure 35-22. Hepatocellular carcinoma and metastases in a 63-year-old woman.

A, Contrast-enhanced CT scan demonstrates a large, mixed-attenuation mass of the posterior segment of the right hepatic lobe with thrombus involving the right portal vein and inferior vena cava (IVC).

B, At a more caudal level to that seen in A, lymphadenopathy (arrows) is demonstrated with extension of the IVC thrombus. Multiple venous collaterals are present. Incidentally noted are a large right renal cyst and thickening of the gallbladder wall.

C, T1-weighted image (TR = 350 msec, TE = 20 msec) shows the large, hypointense mass. There is slightly higher signal in the right portal vein and in the IVC.

D, T2-weighted image (TR = 2500 msec, TE = 80 msec) shows that the mass is moderately to significantly hyperintense relative to the remainder of the liver. Abnormal signal intensity of the right portal vein and the IVC is again noted.

Figure 35-23. Multifocal hepatocellular carcinoma in a cirrhotic liver as a result of chronic active hepatitis B. A, Unenhanced CT scan shows two low-density lesions in the right hepatic lobe, one protruding from the liver margin and the other defined by a slightly hypodense peripheral rim (arrows). B, Contrast-enhanced CT scan shows peripheral rim enhancement and heterogeneous internal density. The protruding lesion is at increased risk for rupture.

Figure 35-24. Hepatocellular carcinoma in a 46-year-old man. *A*, Fat-suppression T1-weighted image (TR = 550 msec, TE = 20 msec) reveals the large mass to be predominantly hypointense with central hemorrhage of mixed signal intensity. Regional extension of tumor is present (*arrow*). *B*, T2-weighted image (TR = 2500 msec, TE = 80 msec) reveals the heterogeneous hyperintense mass with low signal intensity in the region of hemorrhage, indicating the presence of hemosiderin. The signal intensity of the ascitic fluid is higher than that of the area of regional spread.

up SPIO, although usually in a heterogeneous fashion, and to a lesser degree than normal liver (Fig. 35-26).

Fibrolamellar Carcinoma

Fibrolamellar carcinoma (FLC) is a slow-growing malignant tumor of hepatocellular origin that arises in a non-cirrhotic liver. Composed of neoplastic hepatocytes separated into cords by lamellar fibrous strands, these lesions have a distinctive histologic pattern with eosinophilic malignant hepatocytes that contain prominent nuclei.^{49, 50, 209} The α -fetoprotein body inclusions that are usually seen in HCC are not present in FLC. A fibrous central scar may be seen in larger lesions.⁴⁹

Grossly, FLC usually arises in a normal liver; only 20%

of patients have cirrhosis.²⁰⁹ Satellite lesions are often seen. FLC may be similar in appearance to FNH because both tumors may have central scars and multiple fibrous septa. Hemorrhage and necrosis are rarely seen in FLC.

FLC usually occurs in adolescents and adults younger than 40 years of age; there is no sex predilection.²⁰⁹ The mean survival (45 to 60 months) is much better than that of HCC (only 6 months), and FLC has more potential for cure (40%) after surgical resection.¹⁶ Most patients with FLC present with pain, malaise, and weight loss. Jaundice may occur if occasional biliary tree invasion is present. In two thirds of patients with FLC, a palpable mass is found.⁷² Usually, α -fetoprotein levels are normal.

Unenhanced CT scans show FLC as a well-defined, low-attenuation mass.^{72, 79} The central scar has a lower-attenuation appearance. Calcifications are common and

Figure 35-25. Hepatocellular carcinoma in a 63-year-old man with cirrhosis. *A*, T1-weighted image (TR = 2000 msec, TE = 90 msec) demonstrates ascites and heterogeneous slightly increased signal intensity involving the right hepatic lobe. *B*, T2-weighted image (TR = 2000 msec, TE = 90 msec) postintra-venous superparamagnetic iron oxide (SPIO) shows the large mass to be defined as increased signal intensity, whereas the liver demonstrates decreased signal intensity. A satellite lesion is now demonstrated (*arrow*).

Figure 35-26. Hepatocellular carcinoma. A, Unenhanced T2-weighted image demonstrates a 3-cm lesion next to the gallbladder. B, T2-weighted image after superparamagnetic iron oxide (SPIO) administration demonstrates signal loss.

may occur within the scar in a stellate pattern. After IV contrast administration, enhancement of the tumor occurs because of its perivascularity (Fig. 35-27A).^{72, 79}

MRI shows FLC to be isointense relative to normal liver on T1-weighted images (Fig. 35-27B).^{162, 256} On T2-weighted images, it remains isointense to slightly hyperintense, occasionally hypointense, relative to liver (Fig. 35-

27C). A distinguishing feature from hepatocellular carcinoma is its lack of hemorrhage and necrosis. The central scar of FLC remains hypointense on T1-weighted and T2-weighted images because of its fibrous nature. This hypointensity of the central scar of FLC often aids in differentiating this lesion from FNH, which has a hyperintense central scar.²⁵³

Figure 35-27. Fibrolamellar carcinoma. A, Contrast-enhanced CT scan demonstrates a large, enhancing mass containing a central low-attenuation scar (arrow). B, T1-weighted image demonstrates the mass (arrows) to be isointense to the remainder of the liver. C, T2-weighted image shows the mass to be hyperintense relative to the liver. A central hypointense area represents the fibrous scar (arrows).

Figure 35-28. Intrahepatic cholangiocarcinoma in a 45-year-old man. Contrast-enhanced CT scan demonstrates a large central, predominantly hypointense mass with peripheral enhancement. The lobulated mass encases the inferior vena cava, which remains patent.

Intrahepatic Cholangiocarcinoma

Intrahepatic cholangiocarcinoma (I-CAC), an adenocarcinoma that originates in the small intrahepatic ducts, represents approximately 10% of all cholangiocarcinomas.^{49, 128, 172}

These tumors are usually large, firm masses with abundant fibrous tissue. Rarely do they contain internal necrosis or hemorrhage.²¹⁴ Mucin and calcification are often demonstrated microscopically, and desmoplastic reaction may be prominent.

The second most common primary hepatic malignancy in adults, I-CAC is usually discovered in the seventh decade of life, with a slight male predominance.⁴⁹ Symptoms are often vague until the tumor has enlarged, causing abdominal pain and a palpable mass. Jaundice is rarely a presenting symptom because the tumor arises in the peripheral biliary ducts.

On unenhanced CT scans, I-CAC usually has the appearance of a homogeneous, hyperdense mass.^{33, 109, 113, 254} Mild, diffuse centripetal enhancement is often seen after IV contrast administration, with persistent, small, low-attenuation areas representing internal fibrosis. When these lesions are peripheral, associated capsular retraction may occur as a result of its fibrous nature. Satellite nodules and tumor extension through the hepatic capsule with invasion of adjacent organs may be present. Encasement of large vascular structures, such as the portal and hepatic veins, is often present but usually without tumor thrombus (Figs. 35-28 and 35-29A).

MRI demonstrates I-CAC as a large central mass with irregular borders, hypointense on T1-weighted imaging and hyperintense on T2-weighted imaging relative to the liver (Fig. 35-29B and C).^{63, 211} Small satellite nodules may be

Figure 35-29. Intrahepatic cholangiocarcinoma in a 72-year-old man. A, Contrast-enhanced CT scan demonstrates the central low-density mass to encase the right portal vein. B, T1-weighted image (TR = 330 msec, TE 15 = msec) obtained immediately after intravenous gadolinium (Gd-DTPA) demonstrates peripheral enhancement of the predominantly hypointense lesion. A portion of the mass is defined by a nonenhancing, hypointense rim (arrow). C, T2-weighted image (TR = 2000 msec, TE = 90 msec) shows that the predominantly hyperintense lesion contains an area of decreased signal intensity, which represents fibrosis (F).

seen. On T2-weighted images, large central areas of fibrosis in the mass cause hypointensity and an overall heterogeneous appearance. The periphery of I-CAC may be more hyperintense than its center on T2-weighted images, suggesting the presence of a central scar. Progressive, concentric enhancement is common after IV gadopentetate dimeglumine administration (see Fig. 35–29B). As in CT, this may result in the appearance of delayed enhancement relative to the liver parenchyma. This centripetal enhancement pattern spares central areas of fibrosis and reflects the presence of viable peripheral tumor. The typical finding of vascular encasement without tumor thrombus seen in I-CAC is well demonstrated by gradient-echo images and MR angiography.²¹¹

Biliary Cystadenoma and Cystadenocarcinoma

Two forms of a disease spectrum, biliary cystadenoma and cystadenocarcinoma are rare tumors. They represent only 5% of all intrahepatic cysts of bile duct origin, with most cases corresponding to the bile duct or simple cysts.¹⁷⁹ Cystadenocarcinoma is the overtly malignant form of the disease, whereas cystadenoma has a high propensity for recurrence and malignant transformation.^{108, 274}

The tumors occur most often in middle-aged women and are probably congenital in origin because of the presence of aberrant bile ducts.⁴⁹ Although the tumors are most commonly mucinous, a serous variety is recognized. These tumors contain locules that are lined by columnar, cuboidal, or flattened epithelium. Papillary areas and polypoid projections are often present. Focal calcification within the well-formed wall is occasionally seen. Biliary-type epithelium overlies a compact mesenchymal stroma in the cystadenoma, whereas malignant epithelial cells line the cysts of cystadenocarcinoma.

Grossly, the tumor is usually solitary but is often large, measuring up to 30 cm in diameter.⁴⁹ Multiple communicating locules of varying size are contained within the tumor and have a predominantly smooth lining with papillary excrescences and mural nodules projecting from the cyst wall. There is no consistent distinction grossly between the benign and malignant forms of the disease.

On CT scans, both cystadenomas and cystadenocarcinomas are seen as large, low-attenuation intrahepatic masses, often with thick, irregular walls (Figs. 35–30 and 35–31A).^{4, 39, 131} Although cystadenocarcinomas tend to have more solid components and are more irregular than cystadenomas, these signs are not reliable. The presence of adenopathy or metastatic disease usually indicates cystadenocarcinoma.

MRI shows the multiple locules of cystadenoma or cystadenocarcinoma to be of variable signal intensity on T1-weighted and T2-weighted images, depending on the protein content or presence of hemorrhage within the locules.^{192, 212} Septations are seen as low-intensity bands (Fig. 35–31B and C).¹²⁴

Angiosarcoma

Angiosarcoma of the liver is a tumor that consists of malignant endothelial lining cells, occurring primarily in

Figure 35–30. Biliary cystadenocarcinoma. Contrast-enhanced CT scan shows this large cystic mass of the liver containing mural nodules (arrows), distinguishing it from a large simple cyst.

adults exposed to chemical agents and radiation.^{49, 113, 130} The malignant endothelial cells line vascular channels of sizes vary from cavernous to capillary and attempt to form sinusoids. When associated with thorium dioxide (Thorotrast) exposure, the Thorotrast particles may be found within the malignant endothelial cells.

Grossly, most angiosarcomas are multiple and are characterized by internal hemorrhage.¹³⁰ When the lesion appears as a large single mass, it often has cystic areas of bloody debris and does not have a capsule. Concurrent cirrhosis is common.

A rare neoplasm that is 30 times less common than HCC, angiosarcoma occurs most often in men in the seventh decade of life.¹⁰³ It is associated with previous exposure to radiation, Thorotrast, or toxins such as polyvinyl chloride (PVC), arsenic, and steroids; it has also been associated with hemochromatosis. Patients may present with weakness, weight loss, abdominal pain, ascites, and hepatomegaly. Platelet segregation in a large angiosarcoma may cause thrombocytopenia. Rupture with hemoperitoneum may occur in rare instances.^{104, 148}

On unenhanced CT scans, single or multiple hypodense masses may appear except for slightly hyperdense nodules seen with recent hemorrhage.^{143, 234} After IV contrast administration, a centripetal enhancement pattern similar to that seen with hemangioma has been reported.²³⁴ When related to Thorotrast exposure, the reticular pattern of thorium dioxide (Thorotrast) deposition may be well visualized in the liver, with significantly increased density in the spleen and lymph nodes (Fig. 35–32A and B). If rupture occurs, hemoperitoneum may be demonstrated.¹⁵³

In our experience, circumferential displacement of Thorotrast to the periphery of a nodule is a characteristic finding of angiosarcoma. Even though the literature on the MRI appearance of angiosarcoma is limited,²¹¹ we have found that angiosarcoma usually appears as a hypointense mass relative to the liver on T1-weighted images and is hyperintense on T2-weighted images (Fig. 35–32C and D). Peripheral rim enhancement is present after administration of IV gadolinium, with persistent enhancement, seen in

Figure 35-31. Recurrent biliary cystadenoma in a 37-year-old woman. *A*, Contrast-enhanced CT scan shows the large, predominantly cystic attenuation, multiloculated intrahepatic lesion to contain several surgical clips from a previous resection. *B*, T1-weighted image (TR = 500 msec, TE = 20 msec) shows the mass composed of multiple locules of variable low-signal intensity relative to the remainder of the liver. *C*, T2-weighted image (TR = 2200 msec, TE = 80 msec) shows that the mass consists of varied signal, predominantly hyperintense as a result of the protein content of the locules.

delayed images that may mimic the appearance of hemangioma (Fig. 35-32*E*). The presence of Thorotrast is not detectable by MRI.

Epithelioid Hemangioendothelioma

Epithelioid hemangioendothelioma (EHE) is a very rare malignant hepatic neoplasm of vascular origin.⁴⁹ EHE develops in adults and should not be confused with infantile hemangioendothelioma, which occurs in young children. These tumors are often multiple, consisting of neoplastic cells that infiltrate the sinusoids, hepatic veins, and portal vein branches. Although usually an incidental finding, EHE may occasionally cause jaundice, hepatic failure, and rupture with hemoperitoneum.¹⁰⁷ It is more common in women than men.

The prognosis of EHE is more favorable than that of angiosarcoma, with extrahepatic metastases occurring in only one third of reported cases. Metastatic or synchronous lesions may also be found in the lungs and soft tissues.

On unenhanced CT scans, EHE appears as multiple peripheral nodules that coalesce to form large, confluent, low-attenuation masses.^{168, 201, 258} After IV contrast administration, peripheral portions of the mass become isodense relative to the liver, thus resulting in less sensitive identification of tumor extent compared with that of unenhanced scans. The lesions often cause capsular retraction or flat-

tening and may contain calcifications. A peripheral hypodense hypovascular rim and venous invasion may be seen after contrast administration.

MRI of epithelioid hemangioendothelioma accurately depicts tumor extent.^{168, 258} Variable signal intensity, predominantly low to isointense relative to the liver, has been described on T1-weighted images. On T2-weighted images, the lesions are of heterogeneous increased signal intensity. On both T1-weighted and T2-weighted images, peripheral low-signal-intensity rims are often seen.

After IV Gd-DTPA administration, concentric layers of alternating signal intensity are seen with an outer, nonenhancing hypointense rim that corresponds with the hypovascular, hypodense rim seen with contrast-enhanced CT. Capsular retraction or flattening over the multiple peripheral nodules, which coalesce into confluent masses, is revealed by MRI similar to the images depicted by CT.

Mesenchymal Sarcoma

Tumors that arise in the mesenchymal elements of the liver are very rare. These include angiomyosarcoma, leiomyosarcoma, fibrous sarcoma, malignant fibrous histiocytoma, and rhabdomyosarcoma.^{45, 69, 154} These mesenchymal sarcomas usually appear as large, solitary masses that may be smoothly lobulated and contain fibrous septa, often with central necrosis and hemorrhage.

CT usually demonstrates primary hepatic sarcoma as a

Figure 35-32. Angiosarcoma in a 70-year-old man with history of thorium dioxide (Thorotrast) exposure.

A, Unenhanced CT scan without oral contrast reveals that the spleen is of increased attenuation. High-density Thorotrast is retained in the right hepatic lobe (arrow).

B, Unenhanced CT scan at a more caudal level to that in A shows other areas of high attenuation in the liver as a result of retained Thorotrast and high-attenuation nodes containing Thorotrast in the porta hepatis.

C, T1-weighted image (TR = 500 msec, TE = 15 msec) demonstrates a 1-cm hypointense lesion (arrow) not demonstrated by CT.

D, T2-weighted image (TR = 2000 msec, TE = 80 msec) shows the lesion to be of slightly increased signal intensity (arrow).

E, T1-weighted image (TR = 501 msec, TE = 15 msec) following intravenous gadolinium (Gd-DTPA) demonstrates persistent enhancement of the lesion.

large, noncalcified, low-attenuation homogeneous mass on unenhanced scans. After IV contrast administration, there is inhomogeneous peripheral enhancement. The MRI appearance is nonspecific, with the mass having low signal intensity relative to the liver on T1-weighted images and increased signal intensity on T2-weighted images.²¹¹

Hepatoblastoma

Hepatoblastoma, the most common primary liver neoplasm of childhood, is a malignant neoplasm of hepatocyte

origin that often contains mesenchymal tissues.¹⁰⁵ It is classified histologically as *epithelial* or *mixed (epithelial-mesenchymal)*.⁴⁹ The epithelial hepatoblastoma is composed of malignant fetal and/or embryonal hepatocytes. The mixed hepatoblastoma consists of both an epithelial (hepatocyte) component and a mesenchymal component composed of primitive mesenchymal tissue and osteoid material, cartilage, or both.²⁶⁸

This histologic classification is useful for predicting clinical outcome. The epithelial type, especially that with a fetal hepatocyte predominance, is associated with the best

prognosis.^{94, 268} Tumors with the embryonal epithelial cell type carry a poor prognosis. A rare anaplastic form of hepatoblastoma has the poorest prognosis of all types.⁴⁹

Grossly, the hepatoblastoma is usually a large, solitary, well-circumscribed mass with a nodular or lobulated surface. In 20% of cases, it may be multifocal.⁴⁹ Epithelial hepatoblastomas are homogeneous internally; mixed hepatoblastomas with osteoid and cartilage may have large calcifications, fibrotic bands, and an overall heterogeneous appearance.²⁶⁸

Hepatoblastoma usually is found in the first 3 years of life; the peak incidence is between 18 and 24 months of age. However, it may be present at birth or may develop in adolescents and young adults.⁹⁴ It is more frequent in boys than girls. The child with hepatoblastoma may present with abdominal swelling, often with anorexia or weight loss. The serum α -fetoprotein level is usually significantly elevated. Metastatic disease to the lungs is often present at diagnosis.⁵¹

Hepatoblastomas appear on unenhanced CT scans as large, solid, low-attenuation masses that may contain calcifications.⁵¹ Bands of fibrosis, when present, may cause a lobulated pattern. Calcification is most extensive in the mixed form. Following IV contrast administration, enhancement may be extensive because of the tumor's hypervascular nature. Vascular invasion may be present (Fig. 35-33A).

With MRI, the hepatoblastoma is hypointense relative to the liver on T1-weighted images and hyperintense on T2-weighted images (Fig. 35-33B and C).²¹ Fibrotic septa,

when present, appear as low-signal-intensity bands on T2-weighted images. Vascular invasion when present is well demonstrated by gradient-echo imaging or MR angiography.

Undifferentiated Embryonal Sarcoma

Undifferentiated embryonal sarcoma (UES) is a malignant tumor and the fourth most common hepatic neoplasm of childhood, after hepatoblastoma, IHE, and HCC.²⁴³ It consists of primitive, undifferentiated spindle cells that resemble primitive (embryonal) cells with frequent mitoses and a myxoid stroma. Grossly, UES is a large, usually solitary mass having well-defined margins with an occasional pseudocapsule. Internally, it has various-sized cystic areas that contain necrotic debris, hemorrhage, blood, or gelatinous material.^{102, 243} Predominantly cystic tumors are more common than solid tumors.

UES usually occurs in older children, 6 to 10 years of age, with 90% of patients below age 15 years. UES occurs with almost equal frequency in boys and girls.²⁴³ Presenting symptoms are usually a painful abdominal mass; fever, jaundice, weight loss, and gastrointestinal complaints are less common. Serum α -fetoprotein levels are usually not elevated.

CT shows UES to be a low-attenuation mass that may have a cystic or heterogeneous appearance, depending on the degree of necrosis and hemorrhage present (Fig. 35-34A).²¹⁸ Septa and solid portions of the tumor appear as

Figure 35-33. Hepatoblastoma, mixed type. *A*, Dynamic contrast-enhanced CT scan shows a large mass of the right hepatic lobe of predominantly low attenuation and containing multiple calcifications. Right portal vein invasion (*straight arrow*) and a cystic area of necrosis (*arrowhead*) are present. The inferior vena cava (*curved arrow*) is compressed by a portion of the mass. *B*, T1-weighted image shows the mass to be of predominantly hypointense signal with areas of increased signal intensity that represent hemorrhage (*arrows*). *C*, T2-weighted image shows the lesion to have increased signal intensity with hypointense bands that represent fibrous septations.

Figure 35-34. Undifferentiated embryonal sarcoma in a 15-year-old boy.

A, Contrast-enhanced CT scan demonstrates a very large, central, predominantly low-attenuation mass with a very heterogeneous appearance.

B, Coronal T1-weighted image (TR = 400 msec, TE = 12 msec) demonstrates the large mass to have areas of high signal intensity, corresponding to hemorrhage (arrows).

C, T2-weighted image (TR = 2000 msec, TE = 90 msec) shows the mass to be of predominantly very high signal intensity.

D, After chemotherapy, this contrast-enhanced CT scan demonstrates a significant reduction in the size of the mass.

E, T2-weighted image (TR = 2200 msec, TE = 80 msec) after chemotherapy shows the mass continuing to be of mixed signal intensity. The hypointense rim, which represents a pseudocapsule, is demonstrated as low signal intensity. Following the excellent response to chemotherapy, the mass was successfully resected.

dense bands within the cystic tumor. If a pseudocapsule is present, it may appear as a thin rim of dense tissue that surrounds the predominantly cystic mass.

The MRI appearance of UES has not been reported. In our experience, UES appears as a predominantly hypointense mass relative to the liver on T1-weighted images, with areas of high signal intensity corresponding to areas of recent hemorrhage (Fig. 35–34B). The mass is significantly hyperintense relative to the liver on T2-weighted images, reflecting the predominantly cystic nature of the lesion (Fig. 35–34C). Internal debris and septations are easily seen on T2-weighted images.

Lymphoma

Hepatic lymphoma usually occurs in the setting of systemic lymphoma in both Hodgkin's disease and in non-Hodgkin's lymphoma. Rarely, it may be a primary lesion, almost always of the non-Hodgkin's large-cell type.²²²

Grossly, nodular and diffuse forms of hepatic lymphoma may occur. Secondary hepatic lymphoma of Hodgkin's disease occurs more often as diffuse miliary lesions than as focal masses. Hodgkin's disease of the liver is almost always associated with splenic involvement, with an increased likelihood of hepatic involvement when splenic involvement is extensive.^{30, 91} In both Hodgkin's disease and non-Hodgkin's lymphoma, the portal area is typically involved initially because this is the region where lymphatic tissue of the liver is present.

Although primary hepatic lymphoma was previously found most frequently in middle-aged white men, today it is found with increasing frequency in patients who are immunocompromised, such as organ transplant recipients or patients with acquired immunodeficiency syndrome (AIDS).²³³ The liver may or may not be enlarged, and patients may present with right upper quadrant pain or a tender mass of the upper abdomen.²⁰

CT reveals primary and secondary lymphoma as low-attenuation masses of the liver, often large and well circumscribed.²³¹ Focal solitary or multiple masses may be seen (Figs. 35–35 and 35–36). Diffuse infiltration may or may

Figure 35–35. Primary hepatic lymphoma. The contrast-enhanced CT scan shows a large mass of varying attenuation, with contrast enhancement of the tumor lining the necrotic central component. The outer zone of hypovascular tumor remains relatively unenhanced.

Figure 35–36. Non-Hodgkin's lymphoma in a 34-year-old man. Contrast-enhanced CT scan demonstrates a focal mass of low attenuation that extended into the portal region on more caudal images.

not cause hepatomegaly and may be difficult to distinguish from normal liver tissue (Fig. 35–37). Whereas the specificity of CT for hepatic lymphoma is almost 90%, the sensitivity approaches only 60%, mainly because of the difficulty in detecting the infiltrative form of hepatic lymphoma.^{35, 284}

MRI demonstrates focal masses of hepatic lymphoma to be of low signal intensity relative to the liver on T1-weighted images and of high signal intensity relative to liver on T2-weighted images.²⁷² As with CT, the diffuse infiltrative form of hepatic lymphoma is not reliably detected by MRI.

Metastatic Disease

Hepatic metastatic disease is the most common malignancy of the noncirrhotic liver, surpassed in incidence of focal lesions only by hemangioma, focal fatty change, and simple cysts. Metastases occur 30 times more often than

Figure 35–37. Diffuse infiltrative lymphoma. Contrast-enhanced CT scan demonstrates diffuse involvement of the liver. Lymphadenopathy is present.

other malignancies in the noncirrhotic liver. In the cirrhotic liver, however, HCC remains about nine times more common than metastatic disease.¹⁶¹

The liver is second in prevalence only to regional lymph nodes as a site of metastatic disease. Approximately 25% to 50% of all patients who die of malignant disease have metastatic disease of the liver at autopsy. The most common primary neoplasms to cause hepatic metastases are colon (42%), stomach (23%), pancreas (21%), breast (14%), and lung (13%). A silent primary neoplasm with hepatic metastasis is most often found to be a result of pancreatic, stomach, or lung carcinomas. The highest percentages of liver metastases occur in primary carcinomas of the gallbladder, pancreas, colon, and breast; the lowest occurs in prostate carcinoma.^{59, 60}

In patients who died of metastatic disease of the liver, approximately 50% had signs or symptoms of liver disease. Hepatomegaly (31%) is the most common finding, followed by ascites (18%) and jaundice (14.5%). Liver function tests are very insensitive in the detection of hepatic metastatic disease, with normal results in 25% to 50% of patients with metastases. These results may be abnormal because of parenchymal replacement by tumor, biliary ductal obstruction, chemotherapy, or hepatotoxicity. Therefore, radiologic imaging has become essential in the evaluation of hepatic metastatic disease.^{85, 269, 276}

Hepatic metastases may vary in size, consistency, uniformity of growth, response of surrounding tissue, and vascularity.^{59, 60} Lesions may be infiltrative, expansive, or miliary. The primary source of metastasis and the mode of spread influence all of these factors. Individual metastatic liver lesions may differ greatly in appearance in the same patient because of variations in cellular differentiation, fibrosis, necrosis, hemorrhage, and blood supply (Fig. 35–38). This is most common in the vascular metastatic tumors of renal cell carcinoma, carcinoid, choriocarcinoma, and some types of lung cancer.

A zone of venous stasis may be observed to surround a metastatic lesion, extending up to 1 cm, in approximately 25% of patients.^{59, 60} The zone is uniformly circumferential,

and either all or none of the metastatic lesions show this finding in a given patient. This zone of venous stasis is seen most commonly with lung cancer and least commonly with colon carcinoma.

Tumor thrombi that occlude the portal or hepatic vein may be seen in approximately 7% to 15% of patients with hepatic metastatic disease.^{56, 57} When the large portal veins are penetrated, metastases disseminate throughout peripheral portal branches. When the hepatic veins are penetrated, pulmonary metastases may result.

The vascular supply of liver metastases is almost entirely from the hepatic artery.¹ Although hepatic metastases from gastrointestinal tract neoplasms originally derive their blood supply from the portal vein, their blood supply progressively becomes arterial. If therapeutic arterial ligation is performed, however, the blood supply may revert to the portal vein. Metastases may develop calcification that is detectable by CT scanning in the presence of mucin, necrosis, and phosphatase activity. This is most commonly seen in metastases of mucinous adenocarcinomas of the colon, pancreas, and stomach.

Diagnostic challenges in the radiologic evaluation of metastatic disease include staging and follow-up in patients with a known malignancy and the evaluation of resectability in patients with solitary or few metastases (Fig. 35–39). Dynamic CT during the bolus administration of IV water-soluble iodinated contrast material has gained widespread acceptance as the primary modality in the staging and follow-up of metastatic disease. This technique exploits the attenuation difference between tumor and liver, which varies according to the phase of enhancement.

Most gastrointestinal malignancies are best demonstrated in the *portal-venous phase*, 60 to 70 seconds after the start of contrast injection, when they are hypoattenuating to the liver parenchyma. So-called hypervascular metastases (e.g., neuroendocrine tumors, carcinoid tumor, renal cell carcinoma) are best imaged in the *arterial phase*, 20 to 30 seconds after contrast injection, when they are hyperattenuating to the liver.

Paushter and coworkers found the bolus technique supe-

Figure 35–38. Liver metastases. A, Contrast-enhanced CT scan demonstrates a hypoattenuating lesion in the right hepatic lobe that was too small to characterize. B, Short-interval follow-up shows that the lesion has enlarged and now appears hypoattenuating to liver parenchyma due to the fatty infiltration that developed as a result of chemotherapy.

Figure 35-39. Three-dimensional (3D) imaging of the liver. *A*, Axial multidetector CT (MD-CT) image shows a hypervascular mass in the right hepatic lobe. *B*, A 3D reconstruction of segmented hepatic vessels demonstrates a main tumor-feeding vessel and peritumoral vascular mapping. *C*, A 3D image demonstrates the interrelation of adjacent intra-abdominal organs.

rior to the bolus-plus-drip-infusion technique for detecting metastases.¹⁹⁶ The latter technique results in scanning of the liver during the *equilibrium phase*, when the intravascular and interstitial concentrations of contrast material have equilibrated, yielding reduced difference in attenuation between lesions and normal liver than the bolus technique. Bolus injection rates of 3.0 and 4.5 mL/second produce higher CT hepatic contrast enhancement than those reported previously with other techniques.⁹⁹

On CT scans, metastatic lesions may be hyperdense, isodense, hypodense, hypodense with peripheral enhancement, cystic, complex, calcified, or diffusely infiltrative. The CT appearance depends on tumor size, vascularity, hemorrhage, and necrosis as well as the type of IV contrast bolus and timing of scanning.^{10, 14, 71, 78, 242}

Hypodense metastases usually are hypervascular in nature, resulting from primary neoplasms such as melanoma, carcinoid, renal cell carcinoma, pancreatic islet cell tumor, choriocarcinoma, pheochromocytoma, and thyroid carcinoma. Breast and bronchogenic carcinoma may also occasionally result in hypervascular metastases. During contrast-enhanced CT scanning, the lesions may become isodense to the normal hepatic parenchyma, leading some

authors to recommend that precontrast scans be obtained before contrast is given (Fig. 35-40).²⁷

Some metastases may have a cystic appearance, with an attenuation of less than 20 Hounsfield units (HU). These “cystic” lesions may be seen with adenocarcinomas such as mucinous carcinoma of the colon and cystadenocarcinoma of the ovary (Fig. 35-41). Other neoplasms having rapid growth leading to necrosis and a cystic appearance include sarcoma, melanoma, carcinoid, and lung carcinoma (Fig. 35-42). Occasionally, a fluid-debris level may be present.²⁷⁷

Most liver metastases are hypodense relative to the normal liver. Because these lesions are usually hypovascular, administration of IV contrast material increases the density difference between the lesion and the normal parenchyma. Centrally, low attenuation may be present if a lesion has central necrosis or cystic change (Fig. 35-43). Rim enhancement representing the vascularized viable tumor periphery may be seen. The borders of metastases may be sharply defined, ill-defined, or nodular, and their shape may be ovoid, round, or irregular. Calcifications, when present, are well displayed by CT and are better seen on unenhanced scans (Fig. 35-44).^{18, 227} Portal vein invasion

Figure 35–40. Hypervascular leiomyosarcoma metastases. *A*, Unenhanced CT scan demonstrates a large low-attenuation mass. *B*, Contrast-enhanced CT scan demonstrates central enhancement with a circumferential unenhancing peripheral rim.

Figure 35–41. Mucinous carcinoma of the sigmoid colon and “cystic” metastases in a 56-year-old woman. *A*, Contrast-enhanced CT scan demonstrates multiple low-attenuation lesions of the liver that have a cystic appearance. *B*, A large mass of the sigmoid colon is demonstrated with evidence of regional spread.

Figure 35–42. Liver metastases. *A*, Contrast-enhanced CT scan demonstrates multiple hepatic lesions, with abnormal enhancement involving most of the anterior segment. *B*, T2-weighted image after superparamagnetic iron oxide (SPIO) administration more clearly identifies the margins of the lesions.

Figure 35-43. Metastatic breast carcinoma in a 54-year-old woman. Contrast-enhanced CT scan shows a metastatic lesion having very low attenuation centrally, suggesting necrosis.

Figure 35-45. Extensive gastric adenocarcinoma metastases and portal vein thrombosis in a 68-year-old man. Contrast-enhanced CT scan shows multiple low-attenuation masses of the liver with thrombus present in the right portal vein (*arrow*). Surgical clips are present related to previous partial gastrectomy.

is best displayed after IV contrast administration (Fig. 35-45).

Bernadino and coworkers showed that delayed CT scanning performed 4 to 6 hours after a IV bolus injection of a 60-g dose of iodinated contrast material led to increased lesion detection when compared with conventional dy-

namic bolus-enhanced hepatic CT scanning.¹⁷ The delayed CT scanning technique is based on the normal hepatobiliary secretion of 1% to 2% of the iodine dose, which results in a difference of 20 HU in liver density between precontrast

Figure 35-44. Metastatic carcinoma of the sigmoid colon in a 57-year-old man. *A*, Noncontrast CT scan demonstrates a large area of increased and decreased density of the liver that represents calcifications in a large metastatic lesion. A small amount of perihepatic fluid is present. *B*, Contrast-enhanced CT scan makes detection of the calcifications somewhat more difficult because of enhancement. The low-attenuation lesion, however, is now better defined. *C*, The sigmoid colon carcinoma (*arrow*) responsible for the metastatic lesion is shown.

Figure 35-46. Liver metastases. *A*, CT arterial portography scan demonstrates multiple hepatic metastases. *B*, Unenhanced T1-weighted image also shows multiple metastases. *C*, T2-weighted image, after administration of superparamagnetic iron oxide (SPIO), reveals an additional lesion that was not well visualized on other images.

scans and those obtained 4 to 6 hours later. Iodine secretion is not naturally present in focal benign or malignant hepatic lesions not containing hepatocytes. Therefore, this technique results in lower attenuation of the lesion compared with the increased attenuation of the adjacent liver (Fig. 35-46). If liver function is abnormal, as in the setting of biliary obstruction or diffuse hepatic disease, this technique may be less successful.

CTAP, mentioned earlier, is a technique designed to maximize the difference in contrast enhancement between normal hepatic parenchyma (which receives approximately 75% to 80% of its blood supply from the portal vein), and hepatic neoplasms (which receive their blood supply from the hepatic artery). Iodinated contrast material is injected through a catheter placed in the superior mesenteric artery. This enhances normal hepatic parenchyma, although most hepatic lesions are hypoattenuating as a result of their predominantly arterial blood supply.

Although CTAP has gained some acceptance as a sensitive preoperative method of detecting liver metastases, with its great strength in its ability to detect lesions smaller than 1 cm in diameter,^{8, 100, 182} a significant false-positive rate, stemming from benign lesions and perfusion variations in normal hepatic parenchyma, persists (Fig. 35-47). Peripheral wedge-shaped and flat perfusion defects are almost always benign. Benign perfusion defects have also been identified in two characteristic locations: (1) in the antero-

medial aspect of the medial segment adjacent to the intersegmental fissure and (2) within the posterior aspect of the medial segment, immediately anterior to the porta hepatis.¹⁹⁷

MRI is also used for staging and follow-up of metastatic disease. The T1 and T2 relaxation times of liver metastases vary greatly, depending on the primary tumor and on the degree of necrosis, hemorrhage, and vascularity. However, the T1 and T2 relaxation times of metastases are longer than those of normal liver and are usually shorter than those of simple cysts and hemangiomas (except in some hypervascular metastases). Many morphologic appearances of liver metastases have been described.

On T1-weighted images, metastatic liver lesions usually appear as low-signal-intensity masses. In some cases, there is a distinct central region of even lower signal intensity, a pattern often seen with larger lesions and with those that undergo necrosis. However, metastases containing mucin, fat, hemorrhage, or melanin may have a relatively high signal intensity on T1-weighted images.²⁷⁷

On T2-weighted images, most metastatic lesions have increased signal intensity. Spherical metastatic lesions with smooth, sharply defined borders and very high signal intensity have been described as having a “light bulb” appearance. This may be due to (1) complete tumor necrosis and liquefaction, (2) true cystic components, or (3) hypervascularity from primary tumors such as pheochromocytoma,

Figure 35-47. Liver metastases. A, Contrast-enhanced CT scan demonstrates two metastatic lesions in the right hepatic lobe. B, CT arterial portography image shows the same two lesions; however, the presence of a flow-related artifact in the left hepatic lobe suggests a third lesion.

carcinoid, and islet cell tumor.^{84, 138, 191, 277} Some metastatic lesions appear to have a central area of high signal intensity surrounded by a rim of somewhat weaker signal intensity. This pattern is also commonly seen in large lesions and in those with necrosis.^{138, 191, 277}

Other metastases have variable increased signal intensity on T2-weighted images with inhomogeneous and featureless contents. These amorphous lesions have outer margins that tend to be round and indistinct.²⁷⁷ Some metastases may change in both size and shape with different pulse sequences. This may be due to peritumoral edema, which is caused by tumor compromise of the circulation of the more peripheral tissues.²⁷⁷

A pattern that is often described in colorectal metastases is a rim or “halo” on T2-weighted images of increased intensity from 2 to 10 mm in thickness, which encircles a lesion of somewhat lower signal intensity. The lower signal intensity may reflect the presence of fibrosis, coagulative necrosis, or mucin. The halo is probably a manifestation of increased water content. Although some suggest that it may represent peritumoral edema incited by tumor cell infiltration, more likely it represents viable tumor and should be considered when one is estimating tumor volume and planning resection.^{138, 191, 277}

Compared with CT or ultrasound, gadolinium-enhanced MRI has been found to be more sensitive in detecting metastases. Compared with CTAP, MRI has similar sensitivity and shows better specificity for malignancy. Indications for MRI include patients for whom iodinated contrast is contraindicated (e.g., a history of serious reaction to contrast medium²⁰⁶) or additional characterization of lesions thought to represent fatty change or hemangioma.⁶¹ With Gd-DTPA, hypervascular metastases can be distinguished from hemangioma because of the specific persistence of contrast enhancement seen in hemangiomas (Fig. 35-48).

Compared with CT and unenhanced MRI, IV SPIO shows improved detection rates of lesions (Figs. 35-49 to 35-51; see Fig. 35-46).²⁹ Compared with CTAP, IV SPIO

is more accurate in detecting metastases. Additional liver specific contrast agents are being evaluated, including Gd-EOB-DTPA, Mn-DPDP, and Gd-BOPTA (Figs. 35-52 to 35-55).

Infectious Lesions

Bacterial (Pyogenic) Liver Abscess

Bacterial abscess of the liver may develop from several routes, most commonly via the biliary tree, secondary to ascending cholangitis from benign or malignant biliary obstruction.^{6, 121} Other sources of abscess include:

1. Portal vein or superior mesenteric vein phlebitis related to appendicitis, diverticulitis, pancreatitis, or other gastrointestinal (GI) infectious source.
2. Arterial septicemia caused by endocarditis, pneumonitis, or osteomyelitis.
3. Direct extension from contiguous organs, such as a perforated ulcer, pneumonia, or pyelonephritis.
4. Trauma.
5. Iatrogenic causes.

In patients with diabetes mellitus, a cryptogenic abscess may occur with no identifiable source. Metastases may also become infected.

Anaerobic or mixed anaerobic and aerobic organisms account for most bacterial liver abscesses. Facultative gram-negative enteric bacilli, anaerobic gram-negative bacilli, and microaerophilic streptococci are often the responsible organisms. In adults, *Escherichia coli* is most commonly isolated, while *Staphylococcus* is most often isolated from pediatric liver abscesses.²⁵

Although the incidence of pyogenic abscesses has decreased in the United States, these abscesses do remain the most common infectious lesion of the liver. Individuals between 40 and 60 years of age are most often affected, with a slight female predominance. Tender hepatomegaly, fever, malaise, rigors, weight loss, and nausea and vomiting

Figure 35-48. Liver metastases. *A*, Unenhanced T1-weighted image demonstrates a lesion in the right hepatic lobe. *B*, After administration of gadolinium (Gd-DTPA), the lesion shows rim enhancement. *C*, As the liver parenchyma enhances, the rim of tumoral enhancement becomes less apparent. *D*, On portal venous phase imaging, the rim of enhancement is no longer able to be identified.

Figure 35-49. Liver metastases. *A*, Unenhanced T2-weighted image demonstrates a solitary lesion in the right hepatic lobe. *B*, T2-weighted image after administration of superparamagnetic iron oxide (SPIO) shows a second lesion, anterior to the portal vein, not seen on the unenhanced images.

Figure 35-50. Liver metastasis. *A*, Unenhanced T2-weighted image demonstrates a single bright lesion. *B*, T2-weighted image after administration of superparamagnetic iron oxide (SPIO) reveals loss of signal in the hepatic parenchyma without loss of signal in the lesion.

Figure 35-51. Liver metastases. *A*, T1-weighted image after administration of gadolinium (Gd-BOPTA) demonstrates a nonenhancing lesion with enhancement of the rim and hepatic parenchyma. *B*, T1-weighted image after superparamagnetic iron oxide (SPIO) administration easily displays the lesion.

Figure 35-52. Liver metastases. *A*, Unenhanced T1-weighted image demonstrates multiple hepatic lesions. *B*, T1-weighted image after manganese-DPDP administration shows enhancement of the normal liver with improved conspicuity of the proven liver masses.

Figure 35-53. Metastases. *A*, Enhanced CT scan demonstrates multiple hypodense hepatic lesions. *B* and *C*, T1-weighted MR image after gadolinium (Gd-BOPTA) administration in portovenous and delayed phases. Delayed imaging identified many more lesions.

Figure 35-54. Metastases. *A*, Unenhanced T1-weighted MR image demonstrates multiple hepatic lesions. *B*, T1-weighted MR image after manganese-DPDP administration identified additional lesions.

Figure 35-55. Metastases. *A*, Unenhanced T1-weighted MR image demonstrates few low-signal-intensity lesions. *B*, T1-weighted MR image after gadolinium (Gd-EOB-DTPA) administration in the arterial phase shows ring enhancement of the lesions. *C* and *D*, The lesions were much more conspicuous on delayed imaging.

are the most common signs and symptoms of pyogenic liver abscess. Leukocytosis, elevated serum alkaline phosphatase, hypoalbuminemia, and prolonged prothrombin time are the most common laboratory findings.^{25, 54, 199}

Abscesses that are of biliary origin are usually multiple, involving both hepatic lobes in 90% of cases. Abscesses from portal vein sources are often solitary, with 65% occurring in the right lobe, 12% in the left lobe, and 23% in both lobes. This distribution has been attributed to the pattern of mesenteric blood flow in the portal vein.¹⁹⁹

Treatment of pyogenic liver abscess includes elimination of the abscess as well as the source of infection. Therapeutic options for abscess treatment include surgical drainage, antibiotics alone, percutaneous aspiration with antibiotics, and percutaneous catheter drainage with antibiotics. Complications of pyogenic liver abscess include septic shock, secondary infection to other organs, perforation with peritonitis, and fistula formation.

CT has greater than 90% sensitivity for the detection of hepatic abscesses, which appear as low-attenuation, rounded masses on both noncontrast and contrast-enhanced scans (Figs. 35-56 and 35-57).⁹⁶ The attenuation range between 0 and 45 HU overlaps with that of other lesions (e.g., cysts, bilomas, and neoplasms); however, most abscesses have an enhancing peripheral rim or capsule. Although usually sharply defined, some abscesses have a

Figure 35-57. Pyogenic abscess. *A*, Unenhanced CT scan shows a zone of intermediate densities that surrounds the central low-attenuation cavity. *B*, Contrast-enhanced CT scan reveals the hyperemic peripheral zone to enhance.

lobulated contour and circumferential “transition zones” of intermediate attenuation.¹⁵⁹ The *cluster sign* may also be seen, with small lesions less than 2 cm in diameter clustering together with apparent coalescence into a large abscess (Fig. 35-58).¹¹⁵ These described findings are nonspecific, with aspiration required for diagnosis. Gas bubbles or an

Figure 35-56. Pyogenic abscesses resulting from diverticulitis in a 67-year-old man. *A*, Contrast-enhanced CT scan reveals a low-attenuation lesion near the right portal vein with mild peripheral enhancement. *B*, A second, more peripheral lesion is also present in the right hepatic lobe, also having enhancement. *C*, A diverticular abscess was revealed in the pelvis as the source of the abscesses.

Figure 35-58. Pyogenic abscess. Contrast-enhanced CT scan demonstrates the "cluster" sign with two small lesions adjacent to the large central cavity.

air-fluid level are specific signs but are present in fewer than 20% of cases (Fig. 35-59).⁹⁶ The presence of an air-fluid or fluid-debris level may indicate the formation of an enteric communication with the abscess.

MRI of pyogenic liver abscesses is nonspecific, with hypointensity on T1-weighted images and hyperintensity on T2-weighted images relative to the liver, as with other focal hepatic lesions.²⁶⁵ The abscess cavity may be homogeneous or heterogeneous, depending on its contents and degree of necrosis and debris. The capsule may appear as a low-intensity rim. After IV Gd-DTPA administration, rapid enhancement of the abscess wall is followed by a slower increase in signal intensity centrally.^{227, 267}

Fungal Abscesses

Candidiasis, the most frequently occurring systemic fungal infection in immunocompromised patients, is becoming

more common with the increase in incidence of AIDS and with bone marrow transplantation, chemotherapy, and radiation therapy. At autopsy, hepatic candidiasis is found in up to 70% of patients with acute leukemia and in 50% with lymphoma. Concurrent splenic involvement, or *hepatosplenic candidiasis*, is very common. Detection may be difficult because blood cultures are positive in only 50% of patients.^{73, 90, 250} Although aspiration for culture and diagnosis may be needed, treatment usually is by antifungal therapy alone without percutaneous drainage.

The most common appearance of hepatic candidiasis on CT scans is that of multiple, small, round areas of decreased attenuation for which both precontrast and postcontrast scans are required in order to be visualized (Fig. 35-60). On noncontrast scans, areas of scattered increased density that represent calcification may be seen. Periportal fibrosis appearing as increased attenuation may also be present.^{15, 231, 232}

MRI of microabscesses of the liver and spleen caused by *Candida* shows multiple, small lesions of intermediate signal intensity on T1-weighted images and increased signal intensity on T2-weighted images relative to the liver. Conspicuity of the lesions is improved in patients with increased hepatosplenic iron deposition secondary to multiple blood transfusions. This is because the decreased signal intensity of the liver and spleen creates a dark background that highlights the hyperintense microabscesses.³⁸

Amebic Abscess

Amebiasis occurs most often in tropical or subtropical zones of the world. It is becoming more prevalent in the Western Hemisphere as a result of travel and migration, in institutionalized patients, and in homosexual populations.²⁰⁵ Caused by the protozoan parasite *Entamoeba histolytica*, amebic liver abscess is the most common extraintestinal manifestation of amebiasis.^{93, 118, 129, 205, 230} Amebic liver abscesses result when the parasite crosses the colonic mucosa and enters the portal circulation (most commonly) or

Figure 35-59. Gram-negative pyogenic abscess of unknown etiology in a 52-year-old woman with diabetes. Contrast-enhanced CT scan demonstrates multiple air-fluid levels in this large central hepatic abscess.

Figure 35-60. The patient is an immunocompromised man with leukemia and hepatic candidiasis. Contrast-enhanced CT scan demonstrates multiple low-attenuation foci of the liver.

the lymphatics or when it passes directly into the liver from the hepatic flexure.^{93, 199}

The cavitary amebic abscess occurs as liver tissue is focally destroyed. Initially, the lesion contains necrotic tissue, including the viable organism. As the lesion becomes larger, central cavitation occurs and the active organism lies within the necrotic tissue lining the cavity. Surrounding this layer is an inflammatory zone of hepatic parenchyma that is invaded by the organisms. Centrally, the cavity is often filled by a thick fluid that resembles anchovy paste. Frequently solitary, the abscess is most often located in the right lobe. The preferential occurrence of these lesions in the right lobe is related to the venous drainage from the usually infected right colon, via the superior mesenteric vein to the portal vein.¹⁹⁸ Complications include rupture of the abscess through the diaphragm into the pleural space or the lung or into the pericardium or peritoneum.^{118, 199, 230}

Although serologic testing is often useful for the detection of amebiasis,^{93, 129, 205} percutaneous aspiration is occasionally needed for diagnosis. Biopsy of the abscess wall, which contains the living parasite, is more likely to be diagnostic than is aspiration of the thick, reddish brown, "anchovy paste" fluid. Percutaneous drainage may be helpful in the uncommon situation in which medical therapy fails.^{203, 224, 257, 259}

On CT scans, amebic abscesses of the liver appear as low-attenuation lesions, with the density of a lesion dependent on its stage of development and internal contents.^{96, 202} Lesions that are early in development may have an appearance similar to that of solid tumors, whereas older abscesses are more cystic in appearance. If lesions are multiple, their appearance may vary as a result of different stages of development. On unenhanced CT scans, the zone of inflammation, of variable thickness and density, is isodense to hypodense and usually enhances after contrast administration. A thin outer rim of lower attenuation may surround the enhancing layer, giving the lesion a target appearance, and defines the outer boundary of the inflamed hepatic parenchyma (Fig. 35–61).

On unenhanced MR images, amebic abscesses have a well-defined appearance with a rim of varying signal intensity (Fig. 35–62A and B).^{62, 204} On T1-weighted images, the central cavity is usually of decreased signal intensity relative to the normal liver. The central cavity has increased signal intensity on T2-weighted images and often is surrounded by a ring of higher signal intensity that corresponds to the reactive zone. Adjacent high signal intensity on T2-weighted images is thought to represent edema. After Gd-DTPA administration, the hyperemic reactive zone demonstrates enhancement similar to that seen with contrast-enhanced CT (Fig. 35–62D). After successful medical therapy, MRI shows a reduced signal intensity of the hyperintense area that surrounded the abscess cavity on T2-weighted images.

Echinococcal Disease

Hydatid disease of the liver, caused by the larvae of a tapeworm, has two forms. The cystic form, caused by *Echinococcus granulosus*, is more common, occurring in

Figure 35–61. Amebic abscess. Contrast-enhanced CT scan shows that the peripheral low-attenuation rim (arrows) defines the outer limit of the inflammatory wall. An internal septum is present in the large, low-attenuation central cavity.

Mediterranean countries, South America, Australia, and New Zealand. The alveolar form, caused by *Echinococcus multilocularis* (alveolaris), is found in central Europe, the Soviet Union, and other areas of the northern hemisphere, including Alaska.¹³⁶

In echinococcal disease caused by *E. granulosus*, dogs are usually the definitive hosts and sheep are the most common intermediate hosts. In some areas, about 50% of dogs and up to 90% of sheep and cattle may be infected. Humans who ingest material contaminated by dog feces that contain eggs may become intermediate hosts. The eggs hatch within the intestinal tract of the host and penetrate the intestinal mucosa, entering the lymphatics and portal venous system. Most are then filtered by the liver and lungs, thus accounting for the high rate of cyst development in the liver (up to 75% of cases) and lungs.

The cysts, which may be solitary or multiple, grow slowly to reach a large size. The wall of the cyst contains three layers: (1) the *pericyst*, an outer layer formed by the reactive tissue of the host organ; (2) the *endocyst*, an inner germinal layer containing the growing parasite; and (3) the *ectocyst*, an intermediate layer consisting of a proteinaceous membrane.

Daughter cysts may develop within the parent cyst as a result of fragmentation of the germinal layer. Brood capsules, also produced by the germinal layer, give rise to scolices, or infectious miniature tapeworms. When brood capsules and scolices separate from the germinal layer, debris (*hydatid sand*) that falls to the dependent portion of the cyst is formed. Calcification of the ectocyst alone may occur, and when the parasite dies, the true cyst wall (both ectocyst and endocyst) may also calcify or may separate from the pericyst.^{46, 136, 177}

Figure 35-62. Amebic liver abscess in a 60-year-old man. *A*, T1-weighted image (TR = 300 msec, TE = 15 msec) demonstrates a lobulated, low-signal-intensity lesion of the posterior segment of the right hepatic lobe. *B*, T2-weighted image (TR = 2400 msec, TE = 90 msec) demonstrates the lesion to be of high signal intensity relative to the liver. The internal septa are of low signal intensity. *C*, Fat-suppression T1-weighted image (TR = 800 msec, TE = 15 msec) demonstrates the lesion continuing to be of low signal intensity. *D*, Fat-suppression T1-weighted image (TR = 800 msec, TE = 15 msec) after intravenous gadolinium (Gd-DTPA) demonstrates enhancement of the rim and internal septa.

Hydatid cysts of the liver often remain asymptomatic for many years, becoming painful only after growing very large.⁸⁶ They are often discovered incidentally during radiologic imaging performed for other reasons. Most complications from hydatid cysts are related to rupture of the cyst into surrounding structures (biliary tree, pleura, peritoneum).^{23,144} If peritoneal rupture or spillage during surgical excision occurs, a serious anaphylactic reaction may result.

Serologic results for echinococcal disease are positive in more than 80% of patients with hepatic lesions.⁸⁶ Treatment includes antiparasitic drug therapy and surgical removal.^{12,137} Several reports describe successful percutaneous drainage. Medical therapy before drainage is advocated to reduce the risk of anaphylactic reaction in case of accidental spillage.

On CT scans, hepatic echinococcal cysts appear as well-defined round or oval cystic masses with a density near that of water (Fig. 35-63).^{2, 120, 178, 194, 228} Daughter cysts, indicating viability, give the lesion a multilocular appearance (Fig. 35-64A). The outer wall may be outlined peripherally by a line of slightly lower attenuation, or it may

contain calcification. Extensive calcification, however, usually indicates that the lesion is no longer viable. When detached from the pericyst, the true cyst wall may appear as a thin, wavy membrane within the fluid-filled cyst.² After IV contrast administration, the hyperemic ectocyst may enhance slightly.

On MR images, hydatid cysts have decreased T1-weighted signal intensity and increased T2-weighted signal intensity relative to the normal liver.^{101, 155, 262, 279} A low-signal-intensity rim, best seen on T2-weighted images, corresponds to the collagen-rich pericyst. The internal architecture is well demonstrated by MRI, with the daughter cysts being hypointense to isointense on T1-weighted images and isointense on T2-weighted images relative to the hyperintense hydatid fluid and sand of the mother cyst (Fig. 35-64B). The floating membranes seen in a cyst undergoing degeneration appear as low-intensity structures. Intraparenchymal rupture of the wall may be seen as a defect in the low-intensity rim.^{151, 262} Calcifications, when present, are not as well demonstrated by MRI but may produce a signal void.

Figure 35-63. The patient is a 77-year-old woman with echinococcal cysts of the liver and spleen. *A*, Contrast-enhanced CT scan shows a large cyst of the liver with calcification of the cyst wall (*straight arrow*). An area of dense calcification (*arrowhead*) is related to a previous resection. Involvement of the spleen is present. Calcification in the left lung base (*curved arrow*) is related to prior involvement of the pleural space. *B*, Several centimeters more caudal to *A*, additional cysts involving the liver as well as the large splenic cyst are shown.

The alveolar form of echinococcal disease is distinct from the cystic form in several aspects.²⁵³ The main definitive host is the fox, with small rodents being the usual intermediate hosts. Humans become infected by ingesting contaminated materials or by coming into direct contact with infected foxes. This disease, in contrast to the expansile cysts of *E. granulosus*, is characterized by the formation of one or more infiltrative liver lesions that stimulate a granulomatous reaction. Internal necrosis, cavitation, and calcification may be seen within the lesion. The CT and MR imaging appearances of the predominantly solid lesion of *E. multilocularis* are indistinguishable from those of primary or secondary malignant liver neoplasms.^{42, 53, 228} Atrophy of a lobe or segment of the liver may occur when the lesion is located centrally in the liver.²²⁰

Serologic testing and percutaneous biopsy may be useful for diagnosis when alveolar echinococcal disease is suspected. It should be included in the differential diagnosis

of hepatic lesions in patients who live in or have traveled to endemic regions of the world.

Schistosomiasis

Schistosomiasis is a common parasitic infection, with a prevalence of 70% in endemic areas; 10% of patients in these areas experience hepatosplenic involvement.¹⁸⁶ *Schistosoma japonicum* occurs in coastal areas of China, Japan, Formosa, and the Philippines. *S. mansoni* is found in parts of Africa, in the Middle East, in the West Indies, and in the northern regions of South America. *S. haematobium* occurs in North Africa, in Mediterranean countries, and in southwest Asia.

The larvae are shed by snails—the intermediate hosts—into fresh water, where human infection occurs when the parasite penetrates skin or mucous membranes.

Figure 35-64. Echinococcal cyst. *A*, Contrast-enhanced CT scan shows a large cyst in the liver that contains multiple daughter cysts, which indicate viability. *B*, T2-weighted image demonstrates the low-signal-intensity rim that corresponds to the collagen-rich pericyst. The daughter cysts are slightly hyperintense relative to the liver but hypointense relative to the very high signal intensity of the internal hydatid fluid.

The schistosomes migrate via venules and lymphatics, reaching the heart and then passing through the pulmonary circulation. All die except those that reach the mesenteric circulation, maturing within the intrahepatic portal venous system. A granulomatous reaction to the ova occurs, leading to periportal fibrosis and sometimes resulting in portal hypertension. The life cycle of the blood fluke is completed after the mature female worm, which has lived with the male in the portal vein for 10 to 15 years, swims to reach the venules of the urinary bladder (*S. haematobium*) or gut (*S. mansoni* and *S. japonicum*) to lay its eggs. The eggs then pass through the wall of the bladder or intestine to be excreted via urine or feces to infect snails. Schistosomiasis is associated with an increased incidence of hepatocellular carcinoma.

On CT scans, peripheral hepatic septal or capsular calcification is characteristic of *S. japonicum* infection.^{7,171} Gross pseudoseptations with geographic bands of calcification and notches of the liver margin are also noted. Septal, capsular, and amorphous enhancement may be seen after IV contrast administration.¹⁷¹ Periportal low-density areas may be apparent. *S. mansoni* infection appears as round, low-attenuation foci with linear branching low-attenuation fibrotic bands engulfing the portal tracts. These bands occasionally show enhancement after IV contrast administration but do not usually calcify.⁶⁴

MRI features of schistosomiasis infection include the morphologic changes and associated findings of portal hypertension. The regions of calcification and fibrosis may be demonstrated as curvilinear areas of low signal intensity.

Practical Approach to Imaging

Advances in radiologic imaging have led to the detection of additional and smaller hepatic lesions. The detection of lesions smaller than 15 mm may be problematic because of their uncertain clinical significance. A study using CT demonstrated that a single, small (<1.5 cm) lesion was benign in 65% of patients, whereas two to four small lesions were benign in 59% of patients.¹¹⁷ As the number of lesions increased or when a large lesion was present, the likelihood of malignancy increased. Even when an extrahepatic malignancy was present, 51% of these small lesions proved to be benign. In patients with dominant metastases who are under consideration for hepatic resection, the possibility that other smaller lesions may be benign must be considered.

A systematic approach to the differential diagnosis of hepatic mass lesions should include both clinical information and the imaging appearance. The most important clinical information is (1) the patient's age and sex and (2) whether an extrahepatic malignancy, cirrhosis, infection, or immunocompromise is present.

In adults younger than 40 years of age, hemangioma, metastases, FLC, FNH, and HCA are most common. In patients older than 50 years of age, hemangioma, metastases, HCC, I-CAC, and angiosarcoma are most frequently seen.

In children, IHE is seen before 6 months of age, whereas the peak incidences of hepatoblastoma and mesenchymal hamartoma are similar at 18 months. In older children and

adolescents, HCC and UES may be seen. Benign primary hepatic tumors are generally more common in women, whereas malignant primary hepatic tumors are more frequent in men. Overall, metastatic disease is much more common than primary liver neoplasms in adults as well as in the pediatric age groups, except in cirrhotic patients, in whom HCC is more common.¹⁶⁴

Other important clinical information includes the long-term use of steroids or oral contraceptives. Neoplasms related to such use include HCA and (to a lesser degree) FNH, NRH, hemangioma, and HCC.⁴¹ With multiple hepatic masses, note that metastases, although common, are not the only cause of multiple hepatic lesions. Abscesses, cysts, multifocal or diffuse HCC, I-CAC, angiosarcoma, NRH, and hemangioma may all present as multiple liver lesions.

The major goal in the evaluation of a suspected hepatic neoplasm is determining whether it is a *surgical* or *nonsurgical* lesion. The two most common nonsurgical primary hepatic neoplasms in adults are hemangioma and FNH. All other primary hepatic neoplasms are surgical lesions if resectable. In children, hepatoblastoma, UES, HCC, and mesenchymal hamartoma are considered surgical lesions. IHE need not be resected if the patient can survive with supportive care or embolization until the tumor spontaneously regresses.

Liver: Normal Anatomy, Imaging Techniques, and Diffuse Diseases

Elmar M. Merkle, Thorsten R. Fleiter,
Daniel T. Boll, Hans-Juergen Brambs

Normal Anatomy

The liver is the largest abdominal organ. Encapsulated by a dense layer of connective tissue, it resides in the upper right abdominal quadrant, although it can reach into the epigastrium and, sometimes, as far as the spleen. The liver's external structure features a convex diaphragmatic and a concave visceral surface.

The diaphragmatic surface is affixed to a triangular section of the lumbar part of the diaphragm—the bare area, or *area nuda*. The bare area is demarcated by folds of the parietal and visceral peritoneum forming the coronary ligament of the liver. To the right and left, the coronary ligament extends into the right and left triangular ligaments. Toward the ventral aspect of the liver, both limbs of the coronary ligament merge to form the falciform ligament, which serves to divide the liver “anatomically” into right and left hepatic lobes. These ligaments together anchor the liver to the diaphragm. Besides the bare area, only the fossae of the gallbladder and the inferior vena cava (IVC) are not covered by peritoneum.

On the visceral surface of the organ, the individual lobes are demarcated by several fossae and fissures. Two sagittally running fissures are joined by a transverse fissure, forming an H-like structure. The transverse fissure contains the porta hepatis. The left sagittal fissure, which separates the left and right hepatic lobes on the inferior aspect of the liver, contains at its ventral end the ligamentum teres (a remnant of the umbilical vein) and at its dorsal end the ligamentum venosum, which represents the obliterated ductus venosus. (*Note:* In the fetus, the ductus venosus forms a bypass linking the IVC and the umbilical vein.)

The right sagittal fissure contains the gallbladder and, dorsal to it, the IVC. Anterior to the porta hepatis is the slight prominence of the quadrate lobe; posterior to it is the caudate lobe. In the porta hepatis, the hepatoduodenal ligament contains the hepatic artery and portal vein as well as the common hepatic duct, whereby the hepatic artery usually lies between the latter two structures. The hepatic artery carries oxygenated blood to the liver. This blood constitutes about 20% to 25% of the total blood volume in the organ.

The portal vein, in contrast, carries nutrient-rich blood from the digestive system (75% to 80% of total blood volume). The hepatic artery and the portal vein ramify parallel to each other. In healthy subjects, the caliber of the portal vein's branches is larger than the branches of the hepatic artery. Venous return takes place through the hepatic veins, which drain directly into the IVC.

Advances in surgical procedures on the liver have made the anatomic division of the liver (into right, left, quadrate, and caudate lobes) obsolete, and this division has yielded to a functionally oriented segmentation. This segmentation is based primarily on the surgical definition of feasible intrahepatic boundaries of resection.^{6, 13, 21, 59} Computed tomography (CT), magnetic resonance imaging (MRI), and, to a lesser extent, the other cross-sectional imaging techniques provide excellent visualization of the segmental structure of the liver and of the anatomic relationship of hepatic structures to adjacent abdominal viscera.

Centrally placed in each segment is a branch of the portal vein and the hepatic artery as well as a bile duct. The hepatic veins lie between the individual segments. Over the last 50 years, several systems have been proposed for classifying the segments of the liver. Although many of these are similar, the most common is the nomenclature proposed by Bismuth-Couinaud (Figs. 36–1 and 36–2).

In the *Bismuth-Couinaud system*, liver segment I corresponds to the caudate lobe. Because of its vascular supply, this segment is in the unique position of receiving branches from both the main trunk of the portal vein and from its right and left lateral branches. Furthermore, it drains not into the hepatic veins but directly into the IVC.

Liver segments II to VIII are defined by their positions relative to branches of the portal vein and the hepatic veins. The portal vein divides early into a left and a right branch, whereby the left branch supplies segments II through IV and the right branch supplies segments V through VIII. The liver can also be divided by the regions drained by the left, median, and right hepatic veins, which all run obliquely, from ventrocaudal to dorsocranial, into the IVC.

The Bismuth-Couinaud classification also defines a so-

Figure 36–1. Schematic division of liver segments (II to VIII) according to the Bismuth-Couinaud classification. The definition of the individual segments corresponds to the portal venous supply as well as to separation by the right (+), middle (#), and left (*) hepatic veins. Segment I, corresponding to the caudate lobe, because of its special vascularization, is not included. The dashed line represents the horizontal plane separating the cranial from the caudal hepatic segments.

called portal vein plane (see Figs. 36–1 and 36–2). This is simply the transverse plane intersecting the liver at the level of the portal vein bifurcation into right and left branches. In the functional left liver lobe, segment II lies above the portal vein plane to the left of and laterally to the left hepatic vein. Segment III lies beneath this plane, also to the left of and laterally to the left hepatic vein. Segment IV, delineated by the left and median hepatic veins, may be further subdivided into segments IVa (above the portal vein plane) and IVb (beneath this plane).

To the right of and lateral to the median hepatic vein are segments V through VIII, forming the functional right liver lobe. Segment V lies between the median and right hepatic veins below the portal vein plane. Segment VI also lies beneath the portal vein plane, but posterolateral to the right hepatic vein. Segment VII lies directly cranial to segment VI, thus, above the portal vein plane. Finally, segment VIII lies between the median and right hepatic veins above the portal vein plane.

The Bismuth-Couinaud system serves as the basis for describing the location of hepatic focal lesions. Interindividual variability of the vessels, particularly in the right liver lobe, however, is significant. In up to 20% of subjects, there may be reduplication of the right hepatic vein. Data from three-dimensional (3D) reconstructions of the right hepatic vein and of the portal venous system have shown that only an anterosuperior sector and a posteroinferior sector are constantly visualized in the right hepatic lobe.⁶⁹ The scissura between the anterosuperior and posteroinferior sectors shows an angled orientation; that is, its cranial part is tilted posteriorly (~60 degrees), and its caudal part is tilted slightly anteriorly, in relation to the coronal plane. Furthermore, portal branches often cross the plane of the right hepatic vein, and no portal venous plane can be seen separating the anterosuperior and posteroinferior sector; hence, the right hepatic vein cannot serve as a reliable landmark for dividing the anteromedial and posterolateral segments of the right hepatic lobe.

The left liver lobe presents fewer variations in vascular anatomy. Reduplication of the median hepatic vein is seen in about 5% of subjects; of the left hepatic vein, in about 15%.

There may also be some variation in arterial structure, particularly in segment IV. In about 8% of cases, the dorsal portion of segment IV is supplied by the right hepatic artery, hence from the contralateral side, functionally speaking.³³

In about 30% of patients, accessory portal segments, analogous to the caudate lobe (segment I), may be observed; each is supplied directly from the main portal venous trunk or from its right branch.^{5, 69} The presence of a Riedel's lobe (Fig. 36–3), usually resulting from a prominent, inferiorly positioned narrow right lobe of the liver (which significantly extends the expected confines of the liver), should be identified and differentiated from extracapsular extension caused by a liver tumor. When the caudate lobe is prominent, and even with a normal caudate lobe, the inferior caudate extension (or *papillary process*) can simulate a mass in the portocaval region.⁴ One can determine the correct diagnosis by recognizing the continuity of this process with the caudate lobe on contiguous axial sections.

Following segmental hepatic resections, rapid hypertrophy of the remaining liver segments occurs. This results in a distortion of the expected anatomy because the major vessels become displaced by the enlarging segments.

Besides diffuse liver diseases (e.g., hepatic cirrhosis), which produce a nodular contour in the organ, a nodular surface structure may be seen as a normal variation in some subjects (Fig. 36–4). Also important are indentations of the liver's surface resembling the furrows made by the drawing in of a sack with strings, which reflect the structure of the muscular bundles forming the diaphragm and which are more commonly seen in patients with lung diseases (Fig. 36–5).

Because of the significant interindividual variation in vascularity, modern surgical practice has been to reduce reliance on a rigid schematic division of the liver into segments and consider, instead, the patient's individual vascular situation in operations involving segments or even subsegments of the liver.^{19, 46, 65, 67} A liver segment is defined solely by its vascular supply. On the basis of contrast-enhanced helical CT data sets, it is possible to construct

Arterial phase

Portal Venous phase

Figure 36-2. A–E, Dual-phase-contrast, enhanced liver scans on different levels. A, The liver is shown to the right of the midline. Both the left ventricle (LV) and the right ventricle (RV) of the contrast-enhanced heart are clearly seen above the diaphragm in the left side of the chest. The hepatic venous branches are clearly identified, with the right hepatic vein (RHV) coursing between the posterior (P) and the anterior (A) segments of the right lobe. The middle hepatic vein (MHV) courses between the anterior segment (A) of the right lobe and the medial segment (M). The left hepatic vein (LHV) courses between the medial segment (M) and the lateral segment (L) of the left lobe. According to the Bismuth Classification (see arterial phase image, left), the segments 2, 4a, 7, 8 represent the superior aspect of each of the traditional segments. The inferior vena cava (I) enters its intrahepatic portion. B, Level 30 mm caudal to A shows the right portal vein (RP) and left portal vein (LP). Note the anterior branch of the right portal vein (RaP). According to the Bismuth Classification, this is the craniocaudal demarcation level, separating the superior segments (2, 4a, 7, 8) and the inferior segments (3, 4b, 5, 6). The adjacent organs at this level can be easily identified with the stomach (St) to the left and the diaphragm (Da) seen anteriorly (Da) and posteriorly (Dp, indicated by an arrow). S, spleen. C, Level 22 mm caudal to B shows the main portal vein (MP), giving rise to the right portal vein, which bifurcates into anterior branches (RaP) and posterior branches (RpP). The fissure of the ligamentum teres (FLT) with the obliterated remnants of the round ligament is seen, separating the lateral (L) and medial (M) segments of the left lobe of the liver. According to the Bismuth Classification, segments 3 and 4b can be seen in the left liver lobe (lying inferior to the level of the transverse scissura). The right liver lobe is displayed at the junction between the superior and inferior segments of the anterior (A) (8/5) and the posterior (P) part (7/6). The fissure of the ligamentum venosum (FLV) separates the lateral part of the left liver lobe (L) and the caudate lobe (C).

Figure 36-2. *Continued.* *D*, Level 18 mm caudal to *C* shows the main portal vein (MP) in the porta hepatis. The hepatic artery (HA) can be seen anterior and medial to the main portal vein (MP). Note the common bile duct (cBD) (arrow). Bismuth segments 3, 4b, 5, and 6 are caudal to the transverse scissura. *E*, Level 30 mm caudal to *D* shows the superior aspect of the gallbladder (G) and the gallbladder fossa, separating the medial inferior segment (M) 4b and the anterior segment (A) 5. The demarcation between the anterior segment (A), segment 5, and posterior segment (P), segment 6, can only be approximated. Organs bordering the liver are the stomach, colon (Co), duodenum (Du), and right kidney (RK).

3D images of the liver, which assist the surgeon in exact preoperative planning of the procedure (Fig. 36-6).

The 5-year survival rate in patients undergoing resection of both solitary and multiple hepatic metastases can be significantly enhanced if the following three conditions are met:

1. Absence of extrahepatic metastases.
2. Complete excision of all malignant tissue in the liver.
3. Adequate volume of intact residual hepatic parenchyma (at least 30% of the original organ volume).

Figure 36-3. Riedel's lobe (arrows) in a 77-year old woman has resulted from a prominent, inferiorly positioned narrow right hepatic lobe, which significantly extends the expected confines of the liver.

CT Appearance and Imaging Technique

Despite increasing competition from MRI over the last decade, the role of CT in the diagnosis of diseases of the liver has not been significantly affected. Besides the general availability of the method, the dominance of CT is due primarily to its excellent visualization of anatomic relationships and of the liver's position relative to adjacent organs (see Fig. 36-2). These capabilities have been further enhanced by technologic developments that fundamentally affect the method.

Figure 36-4. Protuberant liver (*arrows*) in a 64-year-old man. Both unenhanced (*A*) and intravenous contrast-enhanced (*B*) scans show normal liver parenchyma but do not visualize a tumor responsible for this protrusion.

Figure 36-5. Chronic obstructive pulmonary disease in a 52-year-old woman. On the diaphragmatic surface (*A*), the liver displays a wavelike contour caused by the impression of muscular bundles (*arrows*) of the diaphragm. This phenomenon (*arrows*) is also apparent in more caudally placed sections of the liver (*B*).

Figure 36-6. Volume rendering of the various liver segments defined by the portal venous branches.

The most important of these has been the introduction of single-slice helical CT, in the early 1990s, whose rapid and continuous data acquisition has proved advantageous.³¹ Other important technologic advances over the past decade include the drastic reduction in scan times owing to significantly shorter gantry rotation times (as short as 0.5 second).

Another advance was the development of multiple slice helical CT scanners; as of early 2000, up to sixteen parallel CT slices per tube rotation (with partial reconstructions) could be simultaneously acquired.

The normal CT attenuation of the liver in unenhanced studies varies interindividually between 38 and 80 Hounsfield units (HU). Intraindividually, the normal liver appears homogeneous at CT visualization, and its attenuation exceeds that of the spleen in healthy subjects by about 10 HU.

The relatively large interindividual range in attenuation values is due to the fat and glycogen content of the organ. The increased, diffuse deposition of fat leads to a reduction in attenuation, whereas increased glycogen is reflected in an increase in CT measured density.¹⁷ Valid indications for unenhanced CT scans of the liver include:

1. The search for calcifications (e.g., in primary tumors, such as hemangioendotheliomas (Fig. 36–7); in secondary tumors, such as the calcified metastases of mucinous adenocarcinoma; in postinflammatory calcifications, such as in cases of alveolar echinococcosis; and in intrahepatic CT-opaque bile duct concrements).
2. Visualization of hemorrhage, either subcapsular or into the hepatic parenchyma (Fig. 36–8).
3. Visualization of the Lipiodol distribution pattern following completed intra-arterial embolization of liver tumors (Fig. 36–9).

Because of the biphasic nature of the blood supply to the liver, the pattern of contrast medium uptake in the liver and the associated changes in attenuation values in the hepatic parenchyma over time are complex. Three phases can be differentiated:

1. *Arterial phase.* There is a rapid increase in attenuation values in the abdominal aorta, with a peak occurring immediately following completion of contrast medium injection. Attenuation values in the liver also increase, reaching about 50% of the extent of enhancement in the aorta. As a rule, assuming normal circulatory conditions, the arterial phase begins about 20 seconds after the start of contrast medium injection and lasts 10 to 15 seconds.
2. *Redistribution phase.* Attenuation values within the abdominal aorta decrease rapidly, although enhancement of the hepatic parenchyma, caused by the beginning portal uptake, remains nearly constant or sometimes even slowly increases.
3. *Equilibrium phase.* Attenuation values in both the aorta and the liver slowly and continuously decrease in relation to renal elimination of the contrast medium.

The contrast medium uptake pattern of the liver also depends on the following:

- Amount of contrast medium administered
- Iodine content of the contrast agent
- Site of injection
- Cardiovascular circulation time
- Extent of perfusion of the liver and the other intra-abdominal viscera

At present, application of contrast medium by means of a mechanical injector has become standard; arterial access

Figure 36–7. Hemangioendothelioma of the liver in a 4-day-old infant. A, Unenhanced CT scan shows the typical pattern of fine calcifications (arrows). B, Arterial phase CT scan shows inhomogeneous perfusion, which is more intense toward the organ's periphery (arrows). C, In the portal venous phase, partially thrombosed areas are visualized (arrows).

Figure 36-8. Hepatic bleeding in a 23-year-old woman. *A*, Unenhanced CT scan shows extensive subcapsular hematoma (*long arrows*), which is hyperdense in comparison with normal hepatic parenchyma (*short arrows*). *B*, In the early arterial phase, the CT attenuation values of perfused liver tissue and of the hematoma become almost equal. *C*, In the portal venous phase, the liver becomes hyperdense in comparison with the hematoma. *D* and *E*, Two weeks later, the hematoma appears, much less dense as a result of hemolysis. *F* and *G*, After 3 months, the reduced hematoma appears inhomogeneously hyperintense in both T1-weighted (FLASH gradient-echo sequence TR/TE/NSA/FA/TA 84.2/4.1/1/70°/14) and T2-weighted (TSE sequence TR/TE/NSA/ETL/TA 3000/138/1/29/22) images. ETL, echo train length; FA, flip angle; FLASH, fast low-angle shot; TE, echo time; TR, repetition time; NSA, number of signals averaged; TA, acquisition time; TSE, turbo spin echo.

Figure 36-9. Hepatocellular carcinoma of both liver lobes in a 72-year-old man. *A*, Two tumor nodules (arrowheads) are visualized by contrast-enhanced CT (arterial phase). *B*, One day after transarterial chemoembolization (mitomycin C mixed with Lipiodol), the embolusate is well distributed in both tumor nodules (arrows).

is usually through an 18- to 20-gauge indwelling catheter placed in a cubital vein. Non-ionic contrast media with an iodine concentration of 300 mg/mL are most commonly used and are applied at a flow rate of 1 to 5 mL/second.

The recommended maximum amount of applied iodine is 35 to 45 g; this amount will probably not change significantly despite introduction of the multiple-slice helical CT scanners. This is because the important factor in liver imaging is the degree of maximum contrast enhancement of the hepatic parenchyma, which is determined primarily by the amount of iodine applied, independent of the duration of the examination.^{35, 40}

The concentration of contrast medium actually becomes more crucial in the case of multiple-slice helical CT studies because of the short duration of the arterial perfusion phase. A higher contrast medium uptake can be achieved either by increased concentration or by an increased flow rate. Because increases in the flow rate of the injection are subject to certain limits, the concentration of the contrast medium solution (the total applied amount of iodine being held constant) appear to be the more important parameter. The following example can clarify this principle:

At the end of the arterial phase, following application of 120 mL of contrast medium containing 300 mg/mL of iodine (36 g total iodine), only 80 mL (containing 24 g of iodine) contributes to contrast enhancement within the liver during the arterial phase. When a more highly concentrated contrast medium solution (97 mL of solution containing 370 mg/mL of iodine, total iodine dose = 36 g) at an

identical flow rate and comparable transit time from the cubital vein to the liver is selected, 80 mL of contrast medium is sufficient to perfuse the liver with 30 g of iodine, resulting in a 25% increase in the iodine concentration during the arterial phase.

Because of the short window provided by the arterial phase (10 to 15 seconds) and interindividually variable perfusion conditions (cardiac output, blood volume, visceral perfusion), the need for the capability to track the contrast medium bolus (i.e., using a software program for automatic or semiautomatic determination of expected arrival time of the contrast medium bolus installed directly in the CT unit) becomes apparent.^{34, 36, 56, 57} With its high acquisition speed, multislice CT is superior to single-slice CT in its utilization of this narrow window, permitting visualization of the entire liver during this phase of early contrast medium uptake.

Sequential low-dose scans are obtained at the level of the liver hilum during bolus tracking, usually beginning 10 to 15 seconds after the contrast medium injection is begun. Sequential enhancement values (postcontrast minus precontrast) of the liver, portal vein, and aorta are immediately displayed graphically after image reconstruction. When aortic enhancement reaches a predefined threshold (e.g., 150 HU), scanning begins. The lag time between in vivo contrast enhancement, graphic display on the console, and subsequent initiation of helical scanning is less than 5 seconds.

cols for single-slice and multiple slice CT units, respectively.

The introduction of helical CT scanning has resulted in the displacement of previously used techniques, such as dynamic stationary CT and angiography-assisted CT.

Dynamic stationary CT uses contrast medium uptake behavior to more precisely characterize a known hepatic lesion by documenting the change in attenuation over time; for example, a slice through the lesion is acquired every 5 seconds. On the basis of the resulting data, it is possible to determine whether a focal hepatic lesion is fed arterially or through the portal vein and whether the lesion is primarily hypervascular, hypovascular, or avascular. On the whole, the method is considered obsolete and is applied only in exceptional cases.

Angiography-assisted CT consists of the introduction of a catheter into the common femoral artery whose tip is then advanced into the common hepatic artery (CT arteriography) or the superior mesenteric artery (CT portography). Once the catheter has been positioned, the patient is transferred to the CT unit. During the CT examination, contrast medium is injected through the intra-arterial catheter at a flow rate of 2 mL/second. (*Note:* For this method, the contrast medium must be diluted with normal saline solution: 1:2 for CT angiography, 1:1 for CT portography.) The delay time is about 6 seconds with CT angiography and about 20 seconds with CT portography. Because of its invasivity, the use of angiography-assisted CT is somewhat restricted today.

MRI Appearance and Technique

Examination of the abdomen in general, and of the liver in particular, has become a versatile technique in recent years. Numerous technical improvements, such as the development of more powerful gradient systems and phased-array body coils, permit breath-hold examination of the liver with both T1 and T2 weighting. To date, the liver has the distinction of being the only organ for which an organ-specific contrast medium—superparamagnetic iron oxide (SPIO)—has been developed and approved by the U.S. Food and Drug Administration (FDA). These advances have underscored the significant potential of hepatic MRI not only for tumor detection but also for tumor characterization.

Indications for MRI of the liver include:

1. Characterization of hepatic lesions of uncertain histology.
2. Determination of the extent and segment localization of hepatic malignancies prior to planned partial liver resection.
3. Follow-up in cases of known primary or secondary hepatic malignancies.

In current practice, hepatic MRI studies are performed using phased-array body coils with the patient supine. If a dynamic contrast-enhanced examination is planned, it is best to place an indwelling cannula intravenously in an antecubital vein before the examination is begun. The cannula is then attached by an extension to a contrast medium injection pump that is operated directly from the control room.

Despite the multiplanar imaging that is possible with MRI, axial slices remain standard in hepatic imaging, which also facilitates comparison with any previous CT scan findings that may have been obtained. Should any questions remain, axial images can be supplemented with coronal or sagittal slices. The standard MRI examination of the liver includes native T1-weighted and T2-weighted sequences. The examination technique for MRI systems using medium (0.5 tesla [T]) and high (1.0 to 1.5 T) field strengths is discussed next.

T1-Weighted Imaging

Multislice gradient-echo (GRE) sequences are considered the standard today, particularly in systems with high field strengths. In healthy subjects, MRI visualization reveals the liver to be homogeneous and hyperintense in relation to the spleen (Fig. 36-10). GRE sequences permit examination of the patient in breath-hold technique, and because of the very short echo time (TE), about 4 msec, T1-weighted contrast is very good. Depending on the capabilities of the gradient system, it is possible to acquire between 5 and 25 slices per breath-hold; hence, the entire liver may be scanned in one to three breath-hold phases.

If rapid GRE sequences are not available, spin-echo (SE) techniques or GRE sequences with multiple data transfers represent viable alternatives. These methods, however, extend the required examination time to several minutes. On the other hand, multiple data transfer results in a reduction in motion artifacts while at the same time in-

Figure 36–10. Solitary hemangioma of the liver (arrow) in a 44-year-old woman. In the first echo of the T2-weighted turbo spin-echo (TSE) sequence (A) (TR/TE/NSA/ETL/TA 5136/83/3/9/405), a hypointense lesion in segment VI, in the second echo (B) (TR/TE/NSA/ETL/TA 5136/165/3/9/405), continues to increase in signal relative to the surrounding parenchyma, as is typical of hemangioma. (C) The hemangioma is also clearly visualized on the breath-hold T2-weighted TSE sequence (TR/TE/NSA/ETL/TA 3000/138/1/29/22). On T1-weighting, the hemangioma appears hypointense on unenhanced scans (D) but hyperintense after application of gadolinium-pentetic acid (Gd-DTPA) (E) (FLASH gradient-echo sequence TR/TE/NSA/FA/TA 84.2/4.1/1/70°/14).

creases the signal-to-noise ratio with consecutive improvement of contrast, image quality, and recognition of anatomic details.

Because the T1 relaxation time depends on the magnetic field strength (Table 36–3), sequence parameters differ for medium and high field strengths:

1. *Medium.* A repetition time (TR) of 250 to 350 msec at a TE of 10 to 15 msec for SE sequences (5 to 10 msec for GRE sequences) is recommended.
2. *High.* The TR must be increased to 400 to 500 msec with SE sequences.

If the TE is adjusted for T1-weighted GRE sequences, scans can be obtained with water and lipid protons either *in-phase* or *opposed-phase*.^{43, 44, 51} On in-phase images, the signal from both water and fat protons contributes to tissue signal intensity. On opposed-phase images, signal from fat protons cancels that of water protons.

The choice of TE for in-phase images and for opposed-phase images depends on field strength: using a 1.5-T high field system, the TE is 4.4 msec and 2.2 msec for in-phase and opposed-phase images, respectively (mid-field: in-phase TE = 14 ms, opposed-phase TE = 7 msec). This

Table 36–3. Tissue Relaxation Time of Normal Liver and Focal Liver Lesions

Tissue	Mid Field (0.5 T)		High Field (0.1–1.5 T)	
	Relaxation Time*		Relaxation Time*	
	T1 (msec)	T2 (msec)	T1 (msec)	T2 (msec)

technique is useful in evaluating focal or diffuse fatty infiltration to detect lesions and characterize tissue (e.g., *incidentalomas* in the adrenal glands). Usually, the boundaries between tissues with different water or fat content appear black on opposed-phase images.

T2-Weighted Imaging

There are no significant differences between medium and high magnetic field strength that would affect the choice of T2-weighted imaging parameters. T2-weighted images may be obtained with conventional SE sequences using a long TR and a long TE or a combination of two different TEs, one in the range of 70 to 80 msec (first echo) for lesion detection and the other TE of 140 to 160 msec (second echo) for lesion characterization.

Because of the long acquisition times, conventional SE sequences have been increasingly replaced by rapid sequences in recent years. In turbo SE sequences, multiple echoes can be acquired per excitation, each of which can be phase-coded differently. Acquisition time is reduced by the factor of the acquired echoes. In Figure 36-10C, echo train length = 29; that is, the acquisition time is reduced by a factor of 29 from 10 minutes 38 seconds to 22 seconds; thus, an examination in a breath-hold technique is possible in instances of inadequate local resolution.

With the so-called single-shot techniques, such as rapid acquisition with relaxation enhancement (RARE) or half-Fourier acquisition single-shot turbo SE (HASTE) sequences with an echo train length of more than 100, acquisition times may fall below 1 second per image in certain cases. The lesion-liver contrast on these images is compromised but may be improved with fat-suppression techniques or with an inversion recovery prepulse that provides

short inversion time, inversion recovery-like additive T1-weighted, proton density-weighted, and T2-weighted contrast.²⁰

Echoplanar MRI (EPI) may also be able to replace slower T2-weighted sequences for some indications and might be able to contribute additional diagnostic capabilities, such as lesion characterization, although its routine use in liver imaging had not been recommended by early 2000.

Use of Intravenous Contrast Agents

Various intravenous (IV) contrast agents have been developed to improve the diagnostic capabilities of hepatic MRI. At present, only the nonspecific extracellular gadolinium chelate agents, SPIOs, and manganese-based hepatobiliary agents have been approved for use in the United States.

Nonspecific Extracellular Gadolinium Chelate Agents

With regard to their method of application and their in vivo pattern of distribution, these agents are comparable to non-ionic radiographic contrast media but with a much better biologic tolerability. Although these contrast media were used infrequently in abdominal studies, their use has become increasingly routine in recent years as part of dynamic triphasic examinations. After bolus administration of a gadolinium chelate, at 0.1 mmol/kg of body weight, rapid GRE images are acquired in the arterial (20 to 60 seconds), portal venous (60 to 100 seconds), and equilibrium (5 minutes) phases (Fig. 36-11). The timing of data acquisition can be optimized by precisely determining the

Figure 36-11. A-E, Hepatocellular carcinoma in a 65-year-old man. The pseudocapsule (arrow) appears dark in the unenhanced T1-weighted (FLASH gradient-echo sequence TR/TE/NSA/FA/TA 84.2/4.1/1/70°/14) (A) (0s) but continuously increases in signal (B-E) beginning with the portal venous perfusion phase (35 seconds).

Figure 36–12. Simple liver cyst (arrow) in a 32-year-old woman appears hyperintense in the T2-weighted image (TSE: TR/TE/NSA/ETL/TA 3000/138/1/29/22). A, Forty minutes after administration of an iron-containing contrast medium (B), images generated at unchanged sequence parameters show significant reduction of the liver signal intensity caused by uptake of iron in Kupffer's cells. Also of interest is the drop in signal intensity in the spleen.

individual circulation time with a bolus tracking system using 2.0 mL of a gadolinium contrast agent.¹⁸

Superparamagnetic Iron Oxides

Ferrumoxides are administered as an intravenously injectable colloid, associated with dextran. The colloid is taken up by the Kupffer cells (which make up 2% of the liver volume) as a part of the reticuloendothelial system. Liver uptake is approximately 80% of administered ferrumoxides; the remaining 20% is stored in the spleen and bone marrow. The iron uptake in the macrophages causes local magnetic field inhomogeneities with a decrease in liver signal intensity caused by shortening of T2 relaxation time. Ferrumoxides, diluted with a 5% dextrose solution, are administered intravenously at least 30 minutes before imaging at a dosage of 10 $\mu\text{mol/kg}$ of body weight, but imaging can also occur up to 4 hours after administration (Fig. 36–12).⁵³

Hepatobiliary Contrast Agents

Hepatobiliary contrast agents, based on either manganese (Mn-DPDP) or gadolinium (Gd-BOPTA, Gd-EOB-BOPTA), are taken up by the hepatocytes. Unlike the extracellular gadolinium chelates, these liver-specific contrast agents produce long-lasting enhancement, thus providing a wide imaging window after administration.^{28, 52, 72}

Diffuse Diseases of the Liver

Storage Diseases

Fatty Infiltration

Hepatic steatosis is the result of excessive accumulation of triglycerides within hepatocytes. It is seen in association with several clinical disorders, including alcoholic liver disease, diabetes mellitus, obesity, malnutrition, severe hepatitis, corticosteroid use, and chemotherapy. Although it is most commonly a diffuse process, fatty infiltration can also be focal and inhomogeneous, thus mimicking a tumorous mass.

On unenhanced CT scans, fatty infiltration results in a lowering of the attenuation of the liver parenchyma. In normal adults, the attenuation value of the liver is consis-

tently higher than that of the spleen, with a mean difference of 8 HU.⁶³ Milder degrees of diffuse fatty infiltration can be diagnosed when the attenuation value of the liver parenchyma is less than that of the spleen. Marked steatosis leads to a characteristic CT appearance in which the attenuation of the liver is even lower than that of the blood vessels (e.g., the portal venous branches and IVC) (Fig. 36–13).

Although fatty infiltration can be depicted on contrast-enhanced scans, with liver parenchyma seen as having lower attenuation than that of the spleen, contrast images are less reliable and less specific in detecting steatosis. After contrast administration, significant fatty infiltration is a suggested diagnosis if attenuation of the liver is less than that of muscle.

Both focal fatty infiltration and residual foci of normal unaffected liver parenchyma surrounded by fatty infiltration may be confused with a neoplastic lesion (Fig. 36–14). Focal fatty infiltration commonly has a segmental or lobar distribution, often with a straight line margin providing a clue to diagnosis. These large, irregular-shaped lesions typically extend to the liver capsule, usually without associated bulging of the liver contour. In addition, vessels coursing through the area of abnormality are not displaced. Common locations of nodular fatty infiltration are the anterior part of segment IV adjacent to the falciform ligament and the fissure for the ligamentum teres.

Conversely, focal areas of higher attenuation within a region of fatty change may represent neoplastic masses or foci of uninvolved liver tissue (Fig. 36–15).²⁷ The diagnosis of focal hepatic sparing is suggested when a geographic area of higher attenuation is identified in a typical location, such as along the gallbladder fossa adjacent to the interlobar fissure, next to the ligamentum teres, or in a subcapsular location.

MRI is an excellent tool in differentiating nodular fatty infiltration from neoplasms.^{39, 43, 44} Using in-phase and opposed-phase images, the radiologist can readily diagnose fatty infiltration simply by comparing signal intensity. On opposed-phase images, focal fatty infiltration appears as a region of decreased signal intensity; on in-phase images, signal intensity is present in the corresponding area.

Iron Overload

In a discussion of iron storage diseases, congenital and acquired disease forms should be differentiated and the cellular site of iron deposition must be considered.

Figure 36-13. Extensive steatosis hepatis in a 60-year-old woman. Unenhanced CT scan (A) shows attenuation in the liver to be 15 Hounsfield units (HU). This causes the hepatic vessels to appear hyperdense. However, a simple cyst with an attenuation of 8 HU (arrow) is hardly seen. In the arterial phase (B), the cyst remains poorly demarcated and is clearly visualized only in the portal venous phase (C). Of note is the teres ligament, representing the obliterated umbilical vein, which is clearly visible (arrow).

Figure 36-14. Hyperechoic lesion, visualized by ultrasound, in a 60-year-old man with a prior history of colorectal carcinoma. A and B, Unenhanced CT scans show hypodense areas in both liver lobes (arrows) without the impression of tumor with attenuation similar to fat; compare the splenic parenchyma (arrowheads). C and D, Contrast medium application does not lead to visualization of displacement of the blood vessels. These findings are pathognomonic of focal fatty infiltration.

Figure 36-15. Diffuse, fatty infiltration of the liver with focal sparing simulating a neoplastic lesion. Contrast-enhanced CT scan shows a diffuse, low-attenuation appearance of the liver as a result of fatty infiltration. In segment IV, a rounded focus of higher attenuation (arrows) represents a focus of unaffected, normal liver parenchyma. (Courtesy of Richard L. Baron, M.D.)

In human lymphocyte antigen (HLA)-associated primary hemochromatosis, a defect in the intestinal mucosa leads to increased gastrointestinal (GI) resorption of iron. As a consequence, iron is deposited first in the hepatocytes and then, as the disease progresses, in other tissues (e.g., pancreas, GI tract, kidneys, heart, joints and endocrine glands), with resulting destruction of these tissues. The disease is usually manifested during the fourth or fifth decade with hepatomegaly, ultimately leading to cirrhosis of the organ.

Hepatocellular carcinoma (HCC) is a late complication and occurs in up to 30% of cases. Secondary hemochromatosis presents, as a rule, with the same symptoms and is encountered in patients with chronic anemias who have

received multiple blood transfusions. Further disease forms include congenital transferrin deficiency, porphyria cutanea tarda, cirrhosis of the liver, excessive iron ingestion, and complications of portocaval shunting.

The characteristics of hemosiderosis differ. Unlike hemochromatosis, the primary site of iron deposition is not the hepatocytes but, rather, the reticuloendothelial system, including the spleen, lymph nodes, bone marrow, and Kupfer's cells in the liver.

Iron deposition in the various organs can be detected by both CT and MRI. Increased attenuation within the hepatic parenchyma to levels in excess of 70 HU on unenhanced CT scans is considered characteristic for iron overload.^{8, 26} However, mild forms of iron overload (Fig. 36-16) or cases of coexistent steatosis hepatis may appear normal at CT. The differential diagnosis in patients with CT attenuation values within the hepatic parenchyma exceeding 70 HU includes the following:

1. Glycogen storage disease (or hyperalimentation).¹⁷
2. Wilson's disease with increased copper deposition in the liver and brain.
3. Cardiac arrhythmias in a patient taking amiodarone.²⁴
4. A history of thorium dioxide (Thorotrast) application (Fig. 36-17).^{50, 68}

Cisplatin therapy and colloidal gold used in the treatment of arthritis have also been reported to result in increased liver attenuation.^{3, 12}

MRI is much more sensitive and specific, compared with unenhanced CT, in detecting milder forms of iron storage diseases. Signal reduction is due to the paramagnetic effect of the ferric ions (Fe^{3+}), which shortens the T1 and T2 relaxation times of nearby protons.⁶² T2 shortening is the predominant effect and accounts for the reduction in hepatic signal intensity, which is seen best on GRE T2-weighted images (because of the lack of a 180-degree

Figure 36-16. Primary hemochromatosis in a 68-year-old man. In both the T2-weighted image (A) (TSE sequence TR/TE/NSA/ETL/TA 3000/138/1/29/22) and the T1-weighted image (FLASH gradient-echo sequence TR/TE/NSA/FA/TA 84.2/4.1/1/70°/14) before (B) and after (C) application of gadolinium-DTPA (Gd-DTPA), signal intensity is significantly reduced. Unenhanced CT scan (D) shows a normal liver with attenuation of the hepatic parenchyma at 61 HU.

Figure 36-17. Hemangiosarcoma in a patient with a history of thorium dioxide (Thorotrast) exposition. Unenhanced CT scan (A) shows deposition of Thorotrast throughout the entire reticuloendothelial system, particularly in the spleen (dashed arrows), in the perigastric lymph nodes (arrowheads), and in the liver (arrow). In the right liver lobe, the hemangiosarcoma with its cystic appearance and hypodense central sections is seen. The cystic character of the tumor is even more clearly visualized on the T2-weighted MR image (B). (Courtesy of J. Görich, Ulm.)

refocusing pulse). In many cases, iron overload within hepatocytes (hemochromatosis) can be distinguished from iron deposition within the reticuloendothelial system (hemosiderosis) on the basis of recognition of extrahepatic signal intensity changes.⁵⁵

In hemosiderosis, the liver and spleen each demonstrate low signal intensity (as seen after IV administration of SPIO containing contrast medium) (see also Fig. 36-12B). In hemochromatosis, however, signal intensity in the spleen is not altered, whereas low signal intensity in the pancreas can be documented.

One study has suggested that GRE imaging to estimate hepatic iron content can obviate the need for percutaneous liver biopsy. In this study, GRE imaging showed a close correlation between the hepatic iron concentration and the natural logarithm of the ratio of the signal intensity of liver to the standard deviation of background noise ($r = -.94$) with a low coefficient of variation (12%).⁷

Vascular Diseases

Budd-Chiari Syndrome

Budd-Chiari syndrome occurs secondary to obstruction of hepatic venous outflow caused by occlusion of the major hepatic veins with or without thrombosis of the IVC^{32, 41}:

Type I involves occlusion of the IVC with or without secondary occlusion of the hepatic veins.

Type II consists of occlusion of the major hepatic veins.

Type III is veno-occlusive disease of the liver, or a progressive thrombotic occlusion of small centrilobular veins.

Venous obstruction may be idiopathic in origin or associated with underlying diseases, including hypercoagulopathy, pregnancy, oral contraceptive use, trauma, obstructing tumors (renal, liver, right atrial, IVC leiomyosarcoma, adrenal), and fibrous webs in the IVC. Clinically, patients present with hepatomegaly and liver dysfunction, which lead to portal hypertension and, ultimately, liver failure.⁶⁰

Classical CT imaging findings are based on alteration in the visualization of vessels and of hepatic parenchymal blood flow, including small or absent intrahepatic veins, a small or constricted IVC, enlarged extrahepatic collateral vessels, and patchy liver enhancement in combination with a normal appearance of the caudate lobe owing to its separate drainage directly into the IVC (Fig. 36-18). The

caudate lobe is often enlarged, whereas the periphery of the liver may be atrophied. In chronic cases, nodular regenerative hyperplasia can occur.

One study described 23 patients with liver nodules who were being monitored for Budd-Chiari syndrome. Whereas 4 patients had HCC with one to three lesions, 19 patients had multiple benign regenerative nodules.⁷¹

Distinguishing hepatic veno-occlusive disease from Budd-Chiari syndrome types I and II is a key point in differential diagnosis. In hepatic veno-occlusive disease, the IVC and main hepatic veins are patent, but the terminal hepatic venules are partially or completely destroyed.

With MRI, an absent blood flow in patients with Budd-Chiari syndrome may be difficult to interpret on SE images because, depending on the sequence parameters chosen and the scan orientation relative to the vessel direction, flowing blood may appear as a signal void or as a flow-related increase in contrast. Depending on age and composition, thrombotic material may also exhibit various appearances at MRI. When cross-sectional images do not provide an unequivocal diagnosis, MRI angiography in most instances can clarify the situation.³²

Portal Venous Thrombosis

Partial or complete thrombosis of the portal vein can be caused by a variety of disorders, most commonly neoplasms (with extrinsic compression or direct invasion), infection, trauma, hypercoagulopathy, and pancreatitis.⁴⁹

Thrombosis is best seen on helical CT scans during the portal venous phase, appearing as a low-attenuation defect in the portal vein. Collateral vessels, characteristically seen in the porta hepatis and referred to as a *cavernous transformation*, are another typical finding.⁴⁵ When portal vein thrombosis is segmental, the liver may show decreased attenuation on unenhanced CT scans and increased enhancement during the arterial perfusion phase, thus mimicking an infiltrating tumor. At MRI, intraluminal thrombi demonstrate variable signal intensities, often appearing isointense on T1-weighted images with increased signal intensity on T2-weighted images.⁵⁴

Liver Infarction

Hepatic infarction is rare, in large part because of the dual blood supply provided by the hepatic artery and the portal vein. It is most commonly seen in liver transplant

Figure 36–18. Hepatomegaly, ascites, and abdominal pain in a boy aged 4 months. *A* and *B*, Unenhanced CT scans reveal an inhomogeneously hyperdense liver. The hypertrophy of the caudate lobe is of interest. *C* and *D*, After contrast medium administration, a nodular, spotty pattern of contrast enhancement is seen. Note the absence of visible hepatic veins.

recipients.²² Other causes include hepatic artery thrombosis, embolism, and occlusion following surgical procedures (e.g., laparoscopic cholecystectomy), hypercoagulopathy, and shock.^{2, 37, 38} It may also be seen in preeclamptic or postpartum patients as part of the HELLP (hemolytic anemia, elevated liver enzymes, low platelets) syndrome (Fig. 36–19).^{37, 74}

The typical CT appearance of liver infarction is a peripheral, wedge-shaped area of low attenuation on contrast-enhanced CT. Larger infarcts may have a more geographic distribution. At MRI, lesions are typically hypointense on T1-weighted images but hyperintense on T2-weighted images. Although the diagnosis of liver infarction is obvious in most cases, it may be confused with focal fatty infiltration, abscess, or even a tumor. It is notable that hepatic infarction does not demonstrate either mass effect or abnormal enhancement. Further, vessels coursing through the lesion (as seen in focal fatty infiltration) are typically *not* seen in hepatic infarction.

Hepatitis and Cirrhosis

Hepatitis can be caused by a variety of disorders; the most common cause is infection. Other causes include ingestion and autoimmune and drug-associated factors. In most cases of hepatitis, the CT and MRI appearances of the hepatic parenchyma are normal. In severe and fulminant cases, however, liver edema may be present, with diffuse lowering of the parenchymal attenuation. Other common CT findings are hepatomegaly, ascites, and splenomegaly (Fig. 36–20). MRI shows diffuse signal reduction on T1-weighted images and diffuse signal increase on T2-weighted images. In general, the value of imaging techniques is minor, and the correct diagnosis is usually made as a result of microscopic findings following percutaneous biopsy of the organ.

Chronic hepatitis may lead to liver *cirrhosis*, representing irreversible hepatic fibrosis bridging the portal tracts. Other conditions leading to cirrhosis include alcohol abuse, hemochromatosis, chemical and drug toxicity, chronic bili-

Figure 36–19. HELLP syndrome in a 23-year-old woman. Unenhanced CT scan (*A*) shows an extensive subcapsular hematoma. After administration of contrast medium (*B*), further hypodense areas corresponding to infarctions are visualized. HELLP, hemolysis, elevated liver enzymes, and low platelets.

Figure 36-20. Autoimmune hepatitis in a 66-year-old woman. *A*, Unenhanced CT scan shows splenomegaly without significant reduction in signal intensity of the hepatic parenchyma. *B* and *C*, After application of contrast medium, ascites becomes more visible. As is typically the case, the liver itself appears normal.

ary obstruction (primary sclerosing cholangitis, primary biliary cirrhosis), infections, and other rare entities. If the inciting cause is unknown, the process is referred to as *cryptogenic cirrhosis*. Liver cirrhosis affects the contour of the organ, the size of the lobes and segments, and may cause benign as well as malignant focal lesions within the liver (Fig. 36-21). Processes associated with cirrhosis include ascites and evidence of portal hypertension.

Splenomegaly is the most common finding of portal hypertension, and varices are also often found. These collateral vessels can be seen as enhancing tortuous vessels in

the paraesophageal and gastric cardiac region, the porta hepatis, in the peritoneal cavity, retroperitoneum, and even passing through the liver via paraumbilical collaterals (Fig. 36-22).

Another common finding in patients with liver cirrhosis is the presence of mesenteric, omental, or retroperitoneal edema, which may be seen in up to 80% of cases (see Fig. 36-21).¹⁰ Edema is usually mild but may be severe in approximately 25% of patients. The CT appearance is patchy in about 65% of patients and diffuse in another third. The appearance is purely infiltrative in most cases

Figure 36-21. Cirrhosis of the liver secondary to alcohol abuse in a 68-year-old man. *A* and *B*, Contrast-enhanced CT scans show hypertrophy of the caudate lobe and of segments II and III. Conversely, segments IV to VIII appear unusually small. Other signs of liver cirrhosis include splenomegaly and ascites. *C* and *D*, Abdominal scans show another typical secondary sign: edema in the greater omentum and of the mesentery and retroperitoneum (arrows).

Figure 36-22. Liver cirrhosis and formation of portocaval anastomoses in a 50-year-old woman. In the 2D flow-sensitive, gradient-recalled echo sequence (FLASH TR/TE/NSA/FA/TA 30/7/1/30°/8), axial (A–C) and coronal (D–E) slices show extensive, contorted venous structures within the liver hilus and surrounding the esophagus (arrows). Other criteria for liver cirrhosis include the fine nodular structure of the liver surface and splenomegaly. In addition, the recanalized umbilical vein (arrowheads), which forms a further portocaval collateral, is clearly visible.

but occasionally shows features of infiltration with superimposed masslike nodules.

In some cases of cirrhosis, adenopathy can be seen in the porta hepatis and in the peripancreatic region. Occasionally, these nodes can be large and bulky, mimicking neoplastic involvement. These lymph nodes are the most prominent in cases of primary biliary cirrhosis.⁴⁸

Cirrhosis markedly distorts the hepatic parenchyma, producing either a smooth, nodular, or lobular appearance of the hepatic capsule in most cases.¹⁵ In patients with micronodular cirrhosis, margins that are either smooth or deformed by multiple small nodules are typical. These micronodules underlying the surface of the liver often are not visualized on CT or MR images. At present, high-

resolution transabdominal sonography with a 7.5-MHz transducer may represent the best imaging tool for visualizing these small nodules.⁵⁸ The result of macronodular cirrhosis is coarse nodularity of the margin.

Finally, a lobular liver is usually caused by marked segmental atrophy and hypertrophy rather than by large regenerative nodules.¹⁴ Tremendous overlap in the frequency of smooth and nodular livers among patients with different etiologic mechanisms of cirrhosis usually prevents the physician from being able to distinguish the cause. However, a lobular liver margin is more frequently seen in patients with primary sclerosing cholangitis.¹⁴

Approximately 25% of end-stage cirrhotic livers appear normal in size and shape in all cross-sectional imaging modalities,¹⁵ whereas another third may be diffusely atrophic. Most end-stage cirrhotic livers exhibit a combination of segmental hypertrophy and atrophy,⁶⁶ with the predominant finding being hypertrophy of liver segments I to III (see Fig. 36–21). Focal atrophy is most common in segments IV to VIII and may range from mild to complete involution of the affected segments. Occasionally, segments II/III and VI/VII may be atrophic. This finding is most often seen in patients with primary sclerosing cholangitis. Another rare finding in these patients is a higher attenuation in segment I, causing a pseudotumor in the caudate lobe.¹⁴ Diffuse hypertrophy of the liver, however, may be seen in patients with primary biliary cirrhosis.

In approximately 25% of all patients with end-stage cirrhosis, unenhanced CT and T2-weighted MRI images reveal an inhomogeneous appearance in all parts of the liver.¹⁵ Pathologic examination reveals three causes: (1) diffuse fibrosis, (2) fat, and (3) iron (Fig. 36–23). On cross-sectional imaging, four different patterns of diffuse fibrosis may be seen:¹⁵

1. Patchy, poorly defined regions of low attenuation on unenhanced CT.
2. Thin perlobular bands of low attenuation on unenhanced CT.
3. Thick fibrosis bridging of low attenuation surrounding regenerative nodules (most often in patients with primary biliary cirrhosis).
4. Diffuse fibrosis, causing a high-attenuation perivascular cuffing (usually in patients with primary biliary cirrhosis).

As a result of the reduced portal venous flow in patients with end-stage cirrhosis, contrast-enhanced CT scans during the portal venous phase is usually not helpful in demonstrating fibrosis. On (turbo) SE T2-weighted MRI images, fibrosis appears as an area of high signal intensity. On unenhanced T1-weighted images, fibrosis usually cannot be visualized. Following administration of contrast medium, however, in cases with thin perlobular bands or perivenous cuffing, the fibrous tissue may show mild enhancement on CT and T1-weighted MRI scans.

Another characteristic sign of liver cirrhosis is the development of a spectrum of focal lesions ranging from benign regenerative nodules to malignant HCC.⁶⁴ In 1995, the International Working Party introduced a new nomenclature for hepatocellular nodules, in which the term *dysplastic nodule* replaces such former pathologic descriptions as *adenomatous hyperplasia*, *macroregenerative nodule*, and other terms (Table 36–4).¹

By definition, *regenerative nodules* are present in all cirrhotic livers; however, these nodules are visualized on only 25% of unenhanced CT scans and on approximately 50% of MR images.¹⁶ These nodules usually present as high-attenuation lesions on unenhanced CT scans as a

Figure 36–23. Alcohol-toxic liver cirrhosis in a 56-year-old woman. Unenhanced CT scans (A and B) show reduced attenuation of the hepatic parenchyma, suggestive of steatosis. The parenchyma, particularly in the more caudal sections, is very inhomogeneous. The early arterial contrast phase (C and D) shows irregular, spotty enhancement, which remains visible into the portal venous phase (E and F). Also of note is the significant ramification of the intrahepatic portal vessels.

Table 36-4. Terminology of Hepatocellular Nodules in Cirrhotic Livers

New Terminology	Old Terminology
Regenerative nodule	Regenerative nodule
Low-grade dysplastic nodule	Macroregenerative nodule type I; ordinary adenomatous hyperplasia
High-grade dysplastic nodule	Macroregenerative nodule type II; adenomatous hyperplasia with atypia; borderline hepatocellular lesion
Dysplastic nodule with subfocus of HCC	Early HCC; macroregenerative nodule with microscopic HCC; adenomatous hyperplasia with microscopic HCC
HCC or small HCC (if < 2 cm)	Adenomatous hyperplasia with macroscopic HCC; early advanced HCC; advanced HCC; hepatoma

HCC, hepatocellular carcinoma.

result of their iron or glycogen content or, simply, because they are surrounded by lower-attenuation fibrosis. On portal phase, contrast-enhanced scans, these nodules are rarely revealed. On MR images, these focal lesions can appear hypointense, isointense, or hyperintense on T1-weighted images. An isointense appearance is the most usual, and a hyperintense appearance is the most unusual. On T2-weighted images, they typically appear as hypointense nodules. (Iron causes local magnetic field inhomogeneities with decrease of liver signal intensity because of shortening of T2 relaxation time.)

Dysplastic nodules are premalignant lesions that represent an intermediate step in the pathway of hepatocarcinogenesis in cirrhotic livers.⁶⁴ These lesions are present in approximately 10% of all end-stage cirrhotic livers; unfortunately, however, they are detected only rarely by cross-sectional imaging.¹⁶ If visualized, these dysplastic nodules appear slightly hyperdense or isodense on unenhanced CT scans and isodense or hypodense on all contrast-enhanced (arterial phase, portal phase, and delayed) scans. With MRI, dysplastic nodules appear hyperintense on T1-weighted images and isointense to hypointense on T2-weighted images.^{9, 29}

The incidence of HCC in end-stage cirrhosis is high (range, 3% to 11%).^{11, 16, 42, 47} It occurs most often in cirrhosis secondary to hepatitis.¹⁶ Unfortunately, as many as 40% of all HCC nodules in the cirrhotic liver are not detected by cross-sectional imaging.

Furthermore, carcinogenesis of HCC changes the hemodynamic properties and vascular supply of the tumor nodules resulting in a different enhancement pattern for early and advanced HCCs. In early HCC, the combination of normal hepatic artery degeneration and preserved portal veins results in low attenuation on CT arteriography and isoattenuation on CT during arterial portography. In advanced HCC, the combination of neoplastic (abnormal) arterial development by angiogenesis and obliteration of portal veins results in high attenuation on CT arteriography and low attenuation on CT during arterial portography.³⁰

At MRI, various appearances may be seen on T1-weighted images, ranging from hypointense to hyperintense

nodules. However, almost all HCCs appear bright on T2-weighted images, which allows dysplastic nodules to be differentiated from HCCs.

Small HCCs may be seen only on early gadolinium-enhanced, triphasic, multiphase, dynamic T1-weighted MR images and appear as hyperintense enhancing nodules.⁷³

Another characteristic finding in patients with HCC is the presence of a pseudocapsule, usually consisting of connective fibrous tissue, that appears hypointense on T1-weighted and T2-weighted MRI sequences.²⁵ After administration of gadolinium-containing contrast medium, this pseudocapsule usually shows early enhancement but becomes more prominent on portal venous phase images.

Fibrosis can occur as a confluent mass that replaces even the cirrhotic, regenerating parenchyma in approximately 30% of patients.¹⁶ Focal confluent fibrosis may be seen in all types of cirrhosis, but it occurs most commonly in primary sclerosing cholangitis and least commonly in primary biliary cirrhosis. Important imaging features are as follows:

1. Focal retraction of the liver capsule over the area of fibrosis.
2. Incomplete involvement of liver segments with accompanying atrophy.
3. Characteristic location in segments IVa, IVb, V, and VIII with a wedge-shaped structure radiating from the porta hepatis.

On unenhanced CT scans, focal confluent fibrosis usually appears as a lesion with low attenuation. After contrast medium administration, approximately 50% of the lesions become isoattenuating with the surrounding parenchyma. In rare instances, contrast enhancement of the fibrotic area may simulate a neoplastic process, which typically necessitates percutaneous biopsy. Focal confluent fibrosis appears bright on T2-weighted MR images and hypointense on T1-weighted MR images.

The Gallbladder and Biliary Tract

John R. Haaga, Thomas E. Herbener

The Gallbladder

The gallbladder is a blind pear-shaped pouch lying along the undersurface of the liver. The gallbladder fossa is located in the plane of the interlobar fissure, which lies between the right and left hepatic lobes (Fig. 37-1). It is approximated by a plane passing longitudinally through the middle hepatic vein and the inferior vena cava. Knowledge of the normal gallbladder location aids in differentiating the gallbladder from other structures and in determining whether the gallbladder location is normal or ectopic.

Normal Anatomy

On axial CT images, the gallbladder is a rounded structure with a maximum diameter of less than 4 to 5 cm and an average volume of 30 to 50 mL in the distended state (see Fig. 37-1).⁹⁸ On consecutive axial images, the diameter of the gallbladder usually increases from the more cephalad and medially located neck to the more caudal and typically more laterally located fundus. The neck of the gallbladder may not be readily obvious except on thin-section axial images focused on the porta hepatis or reconstructions (see Fig. 37-2). If contracted, the gallbladder is a smaller tubular structure with a readily discernible wall

(Figs. 37-2 and 37-3). Visualization of the gallbladder wall depends on the degree of gallbladder distention, the clarity of visualization of the gallbladder, or the presence of abnormality. Several values for normal gallbladder wall thickness have been published; these range from 1 to 3.5 mm.^{204, 207, 208, 223, 236} In a series by Whitehouse and colleagues²³⁷ 95% of normal patients had a gallbladder wall thickness of less than 2.8 mm. As with ultrasonography, 3 mm is therefore a reasonable upper limit of normal. The accuracy of the wall thickness measurement will depend on technical factors such as small pixel size, thin-slice collimation, field of view, and appropriate window width and level. In addition, contrast medium administration may aid in defining the wall. There can be enhancement in the gallbladder wall normally after intravenous contrast medium administration, especially if the agent is given in bolus form with dynamic scanning.^{212, 236} A 20-HU increase in gallbladder wall density has been shown in normal gallbladder walls after contrast agent administration.^{119, 236} Enhancement may persist normally in the gallbladder wall up to 2 hours after angiographic studies if more than 37 g of iodine was administered.²¹²

The density of the gallbladder lumen is usually that of water (0 to 20 HU).⁹⁸ After intravascular contrast medium

Figure 37-1. Multislice CT scan of normal gallbladder, with images formatted in 3D plane. Wall of the normal gallbladder is very thin. *Open arrow* shows dilated pancreatic duct.

Figure 37-2. Thin-section axial CT scan showing neck of gallbladder.

Figure 37-3. A, Axial image shows slightly contracted gallbladder with minimal thickening of wall (arrow). B, Coronal, oblique scan reconstructed from data shows long, slightly contracted gallbladder. Area of cystic duct is not seen in this plane but is visualized in following image. C, Coronal oblique scan reconstructed from same data shows the tip of the cystic duct (curved arrow), common bile duct (vertical arrow), and dilated pancreatic duct (open arrow) above the level of the ampulla.

administration, an increase in density of the gallbladder lumen can be seen normally on CT. This is caused by normal hepatic excretion of a small fraction of the contrast agent into the biliary tree. This amount is usually too small to be seen on plain film but can be seen on CT because of the superior contrast sensitivity.^{212, 228} In the setting of abnormal renal function, hepatobiliary excretion of contrast agent may be pronounced with increased density of the gallbladder lumen on CT and plain films (Fig. 37-4).^{203, 212} Certainly, oral cholecystographic agents will increase the density of bile and have been used to perform CT cholangiography.^{89, 90}

Abnormal density of bile in the gallbladder lumen can be seen in various pathologic conditions by CT. Hemobilia can increase the density of bile toward that of blood (50 to 60 HU) as in hepatobiliary trauma or hemorrhage from a neoplasm or vascular abnormality (Fig. 37-5).¹³⁰ Multiple tiny stones may appear simply as increased bile density in the gallbladder lumen if the stones are too small to be individually resolved (Fig. 37-6). However, the most com-

Figure 37-4. CT scan of patient with renal failure shows concentration of contrast material in the gallbladder, which permits visualization of radiolucent gallstones.

Figure 37-5. High-density material in gallbladder representing blood in a patient with excess anticoagulation.

mon cause of increased bile density in the gallbladder lumen is due to cystic duct obstruction secondary to an impacted stone or neoplasm. In acute and chronic cholecystitis, the density of the gallbladder lumen may be increased because of inflammatory debris (Fig. 37-7).^{227, 228} More commonly, however, milk of calcium bile, which is a suspension of calcium carbonate and calcium bilirubinate, will form with cystic duct obstruction (Figs. 37-8 and 37-9). This calcium salt suspension may form from a change in bile alkalinity as a result of cystic duct obstruction and inflammation or may result from secretion of calcium by the injured gallbladder mucosa. It also has been described in the setting of ischemic injury to the gallbladder after transcatheter embolization of the cystic artery.^{39, 228} Milk of calcium bile may completely fill the gallbladder or produce a fluid-fluid level with the denser calcium salt

Figure 37-7. Chronic cholecystitis with contracted gallbladder (arrow) with thickened wall and internal debris with increased density of bile.

Figure 37-8. Gallbladder (G) with milk of calcium bile (arrows).

Figure 37-6. Numerous, very tiny calcified gallstones are too small to be individually resolved.

Figure 37-9. Milk of calcium bile. The intraluminal contents of the gallbladder (G) are hyperdense rather than the normal water-density bile. There is also an obstructing calcified gall stone (arrow) in the gallbladder neck. Bile stasis, often secondary to cystic duct obstruction, is the cause of milk of calcium bile. (Courtesy of Dr. Avram Pearlstein, Mount Sinai Hospital, Cleveland, Ohio.)

Figure 37-10. A, Phrygian cap with small luminal septation (arrow). B, Phrygian cap is the most common variant (arrow). This scan shows thickened wall and numerous low-density stones in the dependent portion.

suspension layering dependently. Blood is usually less dense (less than 90 HU) than milk of calcium bile, which may have a density as high as 1000 HU (Fig. 37-5; see also Figs. 37-25 and 37-103).¹⁰⁶

Congenital Variants

Most anomalies of the gallbladder occur as a result of alterations in budding from the primitive foregut or recanalization of the originally solid gallbladder anlage.¹⁹⁷ Abnormalities in gallbladder form, number, and location occur. Abnormalities in number, such as agenesis or duplication, have been described and are rare.¹⁴⁶

The most common anomalies are those of form, particularly septations of the gallbladder lumen. The most common anomaly of the entire biliary tree is a septation in the distal fundus, which gives the configuration called a phrygian cap (Fig. 37-10). Septations may occur elsewhere in the gallbladder but are less common and may be multiple. Septations may predispose to bile stasis and stone formation.¹⁴⁶ In addition, septations in the gallbladder may cause an appearance that mimics pericholecystic fluid collections (Fig. 37-11).

Figure 37-11. A septation in the gallbladder may give appearance of a pericholecystic fluid collection (arrow).

Figure 37-12. Intrahepatic gallbladder (arrows) surrounded by liver parenchyma infiltrated with fat.

Figure 37-13. Intrahepatic gallbladder (arrow) surrounded by liver parenchyma.

Figure 37-14. A, Retroplaced gallbladder (black arrows) secondary to hypoplasia of the right hepatic lobe. Note small gallstone (white arrow). B, Retroplaced dilated gallbladder on posterior surface of the liver. Note congenital absence of the right lobe.

Anomalies of gallbladder position are rare. The most common ectopic locations are under the left lobe, intrahepatic, transverse, and retroplaced.^{146, 160} The intrahepatic gallbladder is typically subcapsular in location along the anteroinferior aspect of the right hepatic lobe and may be surrounded by fat (Figs. 37-12 and 37-13).²⁵ With hypoplasia, aplasia, atrophy, or hypertrophy of one of the hepatic lobes, the gallbladder may be displaced or rotated abnormally to one side.¹⁴⁶ With cirrhosis and associated atrophy

of the right hepatic lobe, the gallbladder may be retroplaced and be posterior to the liver (Fig. 37-14).¹⁶³ A suprahepatic gallbladder was described with hypoplasia of the right hepatic lobe and eventration of the diaphragm (Fig. 37-15).⁶⁹ Patients with situs inversus will have a gallbladder in the left upper quadrant, and those with polysplenia syndrome may have a spectrum of hepatobiliary anomalies, including a centrally located gallbladder.⁷⁸

Approximately 10% of gallbladders are completely sur-

Figure 37-15. A, Ectopic gallbladder on the anterior surface of the diaphragm. B, Ectopic gallbladder on anterior surface of diaphragm with some atrophy of anterior right lobe. C, Ectopic gallbladder in patient with absence of medial segment of left lobe.

Figure 37-16. A, Mobile gallbladder due to long mesentery, located in mid abdomen. B, Mobile gallbladder with large calcified calculus.

rounded by peritoneum and may have a long mesentery that allows the gallbladder to lie in abnormal locations such as the pelvis (Fig. 37-16). These are the so-called floating gallbladders. These gallbladders may be prone to torsion or volvulus.¹⁹⁷ In one reported case, such a gallbladder presented as a mass in the region of the head of the pancreas (Fig. 37-17).¹⁶⁰

Patients with disease in an ectopic gallbladder may present diagnostic challenges because their symptoms may be atypical particularly as to the location of the pain (see Fig. 37-14). The key to the diagnosis on CT is absence of the gallbladder in its typical location in the gallbladder fossa. Identifying the abnormally located gallbladder is imperative to ensure the appropriate surgical approach if needed.

Cholecystitis

The findings on CT of cholecystitis are individually nonspecific. Gallbladder wall thickening, gallbladder distention, gallbladder wall enhancement, gallstones, and pericholecystic fluid can be seen in both acute and chronic cholecystitis but also in other conditions such as gallbladder carcinoma. The overall specificity of CT depends on both the constellation of radiographic findings and the appropriate clinical setting. Because the clinical presentation of patients with cholecystitis is often unclear, CT may be the first examination performed. Knowledge of the characteristics of cholecystitis on CT will be helpful for appropriate diagnosis.

Acute Cholecystitis. The most common finding on CT

Figure 37-17. A, The ectopic, floating gallbladder appears as a mass in the region of the head of the pancreas. Associated indentation of the medial wall of the contrast medium-filled duodenum is seen. B, Endoscopic retrograde cholangiopancreatography (ERCP) reveals normal pancreatic and common bile ducts. The normal contrast medium-filled gallbladder (GB) is located medial to the air-filled C loop of the duodenum (arrows). (From Morse JMD, Lakshman S, Thomas E: *Gastrointest Radiol* 10:111, 1985.)

Figure 37-18. A, Acute cholecystitis with thickened gallbladder wall (*large arrow*) and debris in the gallbladder lumen (*small arrow*). B, Acute cholecystitis showing edema in the peritoneal fat, thick wall, and focal area of subserosal edema (*arrow*). This is a free-floating gallbladder with a long mesentery, so it appears detached from the liver.

of acute cholecystitis is thickening of the gallbladder wall, often nodular in contour (Fig. 37-18).^{121, 222} Thickening of the wall alone is not specific for acute cholecystitis and can be seen in a contracted gallbladder, cirrhosis, hepatitis, ascites, pancreatitis, congestive heart failure, renal failure, hypoalbuminemia, adenomyomatosis, portal hypertension, multiple myeloma, and gallbladder carcinoma (Fig. 37-19; see also Figs. 37-48, 37-49, and 37-51).^{36, 120, 135, 166, 176} The wall thickness in acute cholecystitis is 3 to 5 mm or more and is caused by mural inflammation and edema. Subserosal edema may present as a hypodense rim surrounding inner, more dense layers of the wall (Fig. 37-20; see also Fig. 37-23).¹⁶⁶ On CT, differentiation of this subserosal edema from pericholecystic fluid may be difficult. Pericholecystic fluid, however, tends to be more focal, and mural edema is more circumferential (see Fig. 37-20). With mural edema, an inner enhancing layer of mucosa and an outer enhancing layer of serosa will “sandwich” the hypodense layer of mural edema.⁸⁸ Pericholecystic fluid will not be surrounded by an enhancing serosa. In addition,

enhancing blood vessels may be seen passing through the mural edema but not through the pericholecystic fluid.⁸⁸

Distention of the gallbladder to greater than 5 cm in diameter can be seen in acute cholecystitis. This, however, is also a nonspecific finding if it is the only abnormality. Diabetes, toxic hepatitis, and distention secondary to neoplastic obstruction of the common bile duct can produce enlarged gallbladders.^{98, 119} In these settings, however, the gallbladder wall is usually not thickened. Distention and wall thickening together are more specific for cholecystitis.

Poor definition of the gallbladder wall and inflammatory changes in the pericholecystic fat are important findings of cholecystitis on CT. The strandlike water and soft tissue densities in the pericholecystic fat represent edema and inflammation (Figs. 37-21 and Fig. 37-22). Transmural inflammation with edema in the tissues around the gallbladder wall will cause loss of sharpness of the wall; and the fatty interface between the gallbladder and adjacent liver parenchyma will be obscured. One report suggests that these pericholecystic changes are one of the most reliable signs of acute cholecystitis on CT.²²¹

Figure 37-19. Thickened gallbladder wall (*between black arrows*) due to hepatitis. Note enhancing mucosa along inner wall (*white arrow*).

Figure 37-20. Gangrenous cholecystitis with findings of edema, wall thickening, and subserosal edema. Note the bulge medially representing local perforation.

Figure 37-21. Acute cholecystitis with pericholecystic inflammatory changes (arrows) and distended gallbladder (G).

Gallstones alone are not themselves a reliable sign of the presence of acute cholecystitis, because they may be seen with or without inflammation of the gallbladder. In addition, CT is not as sensitive as ultrasound for detecting gallstones (see Fig. 37-49). Pure cholesterol stones may not be visualized on CT, owing to the similar density with adjacent bile. Finally, acalculous cholecystitis may demonstrate similar CT findings as acute calculous cholecystitis, such as wall thickening, pericholecystic fluid, and pericholecystic inflammation but without demonstrable gallstones (Fig. 37-23).^{151, 229}

Complicated Cholecystitis. CT is helpful in diagnosing complications of acute cholecystitis because it demonstrates the pericholecystic abnormalities better than ultrasound.²²⁹ Progression to complicated cholecystitis such as empyema, gangrene, and perforation occurs in 25% to 30% of cases of acute cholecystitis.^{133, 222} As transmural inflammation progresses, ischemia and necrosis may develop and lead to perforation. A focal pericholecystic fluid collection in the setting of gallstones, wall thickening, and pericholecystic edema should suggest acute gangrenous cholecystitis (see Fig. 37-20).^{221, 229}

Figure 37-22. Acute cholecystitis (G) with pericholecystic inflammation (arrows) extending into adjacent bowel.

Figure 37-23. Acalculous cholecystitis showing large gallbladder with thick wall (arrow). The patient's symptoms were so severe percutaneous cholecystostomy was performed. Needle is noted entering the hepatic side of the gallbladder.

Fidler and associates⁷³ studied the various findings related to cholecystitis and their usefulness for diagnosis. In 29 cases, they studied the frequency of various findings. The most common findings were wall thickening in 17, pericholecystic stranding in 15, distention in 12, pericholecystic fluid in 9, subserosal edema in 9, high-density bile in 7, and sloughed membrane in 1. When the standard criteria were used, 14 patients were not diagnosed by means of the standard criteria.

Bennett and colleagues²² studied the findings associated with gangrenous cholecystitis in 23 cases and correlated them with comparable groups of simple cholecystitis and normal gallbladder. The four criteria most specific were gas in the wall or lumen, intraluminal membranes, irregular or absent wall, and abscess.

Phlegmon or a complex abscess adjacent to the gallbladder may have a density higher than bile in the gallbladder lumen. In addition, with perforation, gallstones may be detected outside the gallbladder lumen. These stones may erode into adjacent structures such as the duodenum, colon, and biliary tree, causing fistulas. If there is communication into bowel, air may be seen in the gallbladder and biliary tree. Gallstone ileus can occur when a stone erodes into the small bowel with subsequent small bowel obstruction (Fig. 37-24).

Empyema of the gallbladder may not appear differently on CT than uncomplicated acute cholecystitis because pus in the gallbladder lumen may have normal water density. Increased luminal density, however, may be seen as a result of the inflammatory debris. A case of hemorrhagic cholecystitis has been reported with hyperdense fluid in the gallbladder lumen, as a result of hemorrhage (Fig. 37-25).¹¹⁹ Although milk of calcium bile and contrast agent can increase the density of bile in the gallbladder, empyema and hemorrhagic cholecystitis should be another consideration.

Gallbladder Perforation

Kim and colleagues¹²⁷ reported on the appearance of gallbladder perforation and compared findings on ultraso-

Figure 37-24. Gallstone ileus. A, A stone (S) is seen in the gallbladder with a visible fistula between the gallbladder and the adjacent duodenum (white arrow shows defect in medial gallbladder wall). Black arrow shows pericholecystic fluid. B, Pneumobilia (black arrows). C, Stone in second portion of dilated duodenum (arrow). Note dilated small bowel (b) due to distal obstruction. D, Stone in distal small bowel lumen (arrow) causing obstruction with dilated small bowel (b) proximally.

Figure 37-25. Hemorrhagic cholecystitis. The gallbladder wall is thickened (arrowheads), and its intraluminal contents are abnormally increased in density, representing blood mixed with bile. The rounded area of decreased density within the neck of the gallbladder (arrow), is a calculus. (From Jenkins M, Golding RH, Cooperberg PL: Am J Roentgenol 140:1197-1198, © by American Roentgen Ray Society, 1983.)

nography and CT. The findings common to both modalities were the presence of pericholecystic fluid, layering of gallbladder wall, streaky edema in the mesentery, and a bulge or defect in the wall at the site of the perforation. The defect in the wall was seen in 38.5% of cases on ultrasonography and in 69.2% on CT examination.

Emphysematous Cholecystitis. The only single specific sign for acute cholecystitis on CT is gas in the wall or lumen of the gallbladder, as seen in emphysematous cholecystitis.^{5, 145} The gas develops in acute cholecystitis with bacterial infection secondary to gas-producing organism, such as *Escherichia coli*, *Enterobacter aerogenes*, and *Clostridium*. The gas may appear as bubbles in the gallbladder lumen, or it may be within the gallbladder wall, giving a gas density rim to the gallbladder that is pathognomonic (Figs. 37-26 and 37-27). CT is an excellent technique to diagnose emphysematous cholecystitis because it detects and localizes gas easily as a result of its superior contrast and spatial resolution. No intravenous or oral contrast agent is required and, unlike on plain film or ultrasound, bowel gas is usually readily differentiated.

Gallstone Ileus. Gallstone ileus is an uncommon complication of chronic cholecystitis in which a gallstone erodes through the gallbladder wall and into adjacent

Figure 37-26. A, Emphysematous cholecystitis with gas in the gallbladder wall (arrows) surrounding the gallbladder lumen (G). B, Emphysematous cholecystitis with gas extending into porta hepatis (arrows).

bowel, causing subsequent bowel obstruction. The duodenum is the most common site of erosion, with the stone migrating distally in the bowel lumen and causing distal small bowel obstruction.

Patients with gallstone ileus often present with nonspecific abdominal pain. Biliary symptoms are often absent. The preoperative diagnosis is difficult to make. The plain film findings have been described and include the triad of small bowel obstruction, pneumobilia, and an ectopic gallstone. However, not all gallstones are radiopaque on plain film, and pneumobilia may not be present. Therefore, plain film diagnosis may be difficult and is seen in only 30% to 35% of cases.⁹²

The findings on CT have been described and include dilated loops of small bowel, pneumobilia with air in the bile ducts and gallbladder, and a stone within the bowel lumen—usually distal small bowel.⁹²

Mirizzi Syndrome. Mirizzi syndrome is the condition

Figure 37-27. Gram-negative gas forming infection in gallbladder. CT scan shows enlarged gallbladder with thick wall, small amount of air (arrow), and faceted gallstones.

of biliary obstruction of the common hepatic duct at the level of the gallbladder neck caused by inflammation associated with an impacted gallstone in the gallbladder neck or cystic duct (Fig. 37-28). It is typically a complication of chronic cholecystitis. Congenital anomalies of the extrahepatic bile ducts may predispose patients to this condition.²⁰ Because of the inflammation, fibrosis, and distortion of structures at the level of obstruction, both preoperative and intraoperative diagnoses are difficult.

These patients typically present with symptoms suggestive of gallbladder disease and jaundice. Ultrasonography and CT are often the initial examination performed to evaluate such a clinical presentation. On CT, dilated bile ducts may be seen with the common hepatic duct (CHD) dilated to the level of the gallbladder neck or cystic duct (Fig. 37-29).^{20, 24} Often a stone may be seen in the neck or cystic duct at this level. The CHD diameter abruptly decreases below the level of the stone. Nonspecific signs of cholecystitis may be present.

The stone in the neck of the gallbladder or cystic duct may obstruct the CHD as a result of extrinsic compression. However, the stone may erode into the CHD by pressure necrosis, or it may erode into the surrounding tissues of the hepatoduodenal ligament and be detected outside the bile duct. A cholecystobiliary fistula may occur but will be difficult to directly visualize on CT.²⁰ Cholangiography (endoscopic retrograde [ERCP] or percutaneous transhepatic [PTC]) is the gold standard to evaluate for a fistula.

Mirizzi syndrome may mimic a malignancy especially if the stone in the neck of the gallbladder or cystic duct is not visualized. Abrupt change in caliber of the CHD can be seen in malignancy such as cholangiocarcinoma (CCA). PTC or ERCP may demonstrate a stricture in the CHD that also may mimic malignancy. Carcinoma of the cystic duct has been described as mimicking Mirizzi syndrome because of associated CHD obstruction.¹⁸¹ However, CT, especially high-resolution CT, will show no evidence of mass or lymphadenopathy in the setting of Mirizzi syndrome as expected with malignancy; this is an extremely important observation.²⁴

Chronic Cholecystitis. Chronic cholecystitis may have

Figure 37-28. Mirizzi syndrome. *A*, Mild dilatation of the central intrahepatic bile ducts (*arrows*). *B*, Lucent gallstone in the neck of the gallbladder (*arrows*), causing biliary obstruction. *C*, Gallbladder (*G*) with thickened wall because of inflammation (*arrow* indicates normal distal common bile duct).

similar findings as acute cholecystitis, such as wall thickening, stones, and wall enhancement (Figs. 37-29 to 37-31). The gallbladder, however, often is contracted around the gallstones rather than distended. A “porcelain” gallbladder is an uncommon manifestation of chronic cholecystitis where calcium is deposited in the gallbladder wall. The calcium may be found in coarse plaques in the muscularis or as

diffuse punctate foci in the mucosa (Fig. 37-32). Although plain films and ultrasonography may demonstrate a porcelain gallbladder, CT is better at detecting and localizing the calcium to the wall of the gallbladder.¹²² In addition, because of the association of porcelain gallbladder and gallbladder carcinoma, the CT examination should be carefully viewed for any sign of carcinoma (Fig. 37-33).^{79, 106, 175}

Figure 37–33. Gallbladder carcinoma arising from a porcelain gallbladder. *A*, Gallbladder containing dense stones (s) and calcified mural plaque (black arrows) with focal carcinoma in the wall (white arrows). p, ascites. *B*, Diffuse metastatic lymphadenopathy (n) and ascites (p) with peritoneal metastases.

Porcelain gallbladders may, in fact, be removed prophylactically because of the association with carcinoma. Occasionally, the calcified rim of a large gallstone may mimic calcification in the wall of the gallbladder.

Xanthogranulomatous Cholecystitis. Xanthogranulomatous cholecystitis is a rare condition associated with chronic recurrent inflammation of the gallbladder due to gallstones. It is a benign process but may mimic gallbladder malignancy with its slow insidious onset and its appearance on imaging studies. Preoperative diagnosis is rare.^{58, 64}

Pathologically, this process consists of a mixed inflammatory infiltrate in the gallbladder wall with foamy histiocytes, foreign body giant cells, and diffuse fibrotic reaction. This is a similar xanthogranulomatous reaction as elsewhere in the body. Grossly, diffuse nodules may appear in the gallbladder wall, a large "tumor" mass may form, or an ill-defined infiltrative process may occur.⁵⁸

On CT, irregular thickening of the gallbladder wall is the most common abnormality in addition to gallstones. However, a mass may be present in the gallbladder fossa.⁵⁴ The appearance may be impossible to separate from that of gallbladder carcinoma on both ultrasound evaluation and CT. However, no evidence of metastases or biliary dilatation will be seen with xanthogranulomatous cholecystitis.^{58, 64}

Chun and associates⁴⁸ studied the features of xanthogranulomatous cholecystitis and gallbladder carcinoma and to define criteria to differentiate the two. They concluded one can differentiate the two only when the gallbladder is largely occupied by large hypoattenuated nodules. Without such nodules, the thickening and mass effect are indistinguishable.

Hyperplastic Cholecystoses. The hyperplastic cholecystoses are noninflammatory conditions of the gallbladder that consist of benign proliferation of normal tissue of the gallbladder and include cholesterosis and adenomyomatosis. Cholesterosis consists of multiple focal deposits of cholesterol-laden macrophages in the lamina propria of the gallbladder wall and formation of cholesterol polyps. These are very small, however, and not typically seen on CT but better appreciated on ultrasound evaluation.

The CT findings in adenomyomatosis have been described. This condition consists of thickening of the muscular wall of the gallbladder with proliferation of mucosal epithelium and outpouching of the mucosa into or through the wall, forming intramural diverticula. CT demonstrates the gallbladder wall thickening, which may be focal and may show the intramural diverticula especially if an oral cholecystographic agent is administered or if small stones are within the diverticula (Figs. 37–34 and 37–35).^{29, 50, 113, 153} Fatty proliferation in the subserosal portion of the gallbladder has been reported.¹⁵³ Thickening of the gallbladder wall may be the only finding on CT, and exclusion of other processes such as cholecystitis or gallbladder carcinoma may be difficult (see Fig. 37–55).¹¹³

Polypoid Lesions

Furukawa and colleagues⁷⁷ evaluated the use of CT for the detection and characterization of polypoid lesions. They

Figure 37–34. Focal adenomyomatosis (large arrow) in fundus of gallbladder with small gallstones in the lumen (small arrow).

studied a group of 20 patients who had CT examination followed by cholecystectomy. With unenhanced scans, only 40% were detected, whereas 100% were detected in the enhanced studies. The polypoid lesions were classified into three types: pedunculated, sessile, and mass-forming. Cholesterol and hyperplastic polyps were all pedunculated. Adenomyomatosis were mass-forming in the two cases. Adenocarcinomas were sessile in four of five cases and pedunculated in one. Density differences were of no benefit in distinguishing among the various entities.

Postcholecystectomy. After cholecystectomy via laparotomy (open cholecystectomy), CT can be used to evaluate patients with persistent fever, abdominal pain, or abnormal liver function tests. Biliary scintigraphy (DISIDA) and cholangiography will often be the first-line examinations

Figure 37–35. Adenomyomatosis with proliferation of subserosal fat (large arrows), intramural diverticula containing stones (small arrows), and soft tissue mass (G) in gallbladder lumen. (From Miyake H, Aikawa H, Hori Y, et al: Adenomyomatosis of the gallbladder with subserosal fatty proliferation. CT findings in two cases. *Gastrointest Radiol* 17:21, 1992.)

to evaluate for bile leak or duct injury.⁸⁰ However, CT may be used to evaluate for abscess, hematoma, or an unexpected postoperative complication. Subhepatic fluid collections have been shown by ultrasound in 20% of postcholecystectomy patients.¹⁴³ In addition, 44% of such patients have been shown in one series to have bile leaks on DISIDA scans, with the majority being clinically insignificant.²³² CT can identify these collections but unfortunately often cannot differentiate a postoperative seroma, abscess, hematoma, or biloma, unless percutaneous aspiration is performed (Fig. 37–36).

Laparoscopic cholecystectomy is rapidly becoming a popular treatment for gallbladder disease. Typical postoperative changes on CT have been described and include pneumoperitoneum, subcutaneous emphysema, subhepatic fluid collections, ascites, and gallbladder fossa edema.¹⁴³ Small fluid collections in the gallbladder fossa immediately in the postoperative period are common and probably represent small bile leaks because of disruption of ducts of Luschka, which are accessory ducts draining directly from liver parenchyma into the gallbladder (Fig. 37–37). Significant bile leakage is one of the more common postoperative complications and occurs as a result of injury to the extrahepatic bile ducts, leak from the cystic duct remnant, or leak from transection of large unrecognized accessory bile ducts. A DISIDA scan will be the most useful examination in demonstrating the bile leak, and ERCP can define the exact site of leakage. CT will demonstrate a fluid collection in the porta hepatis, subhepatic fluid, or diffuse ascites. Endoscopic management of such leaks has been shown to be nearly 95% successful.²³² If the DISIDA and ERCP are not helpful, CT may be used to examine the patient for other postoperative complications such as abscess or hematoma. Ligation of aberrant bile ducts or unrecognized accessory bile ducts may be demonstrated on CT and has been reported as focally dilated subsegmental intrahepatic bile ducts typically in the posterior portion of the right lobe of the liver.⁴⁹

Figure 37–36. After cholecystectomy, abnormal soft tissue density, with a few small collections of gas (arrows), is present in the region of the gallbladder fossa. On aspiration, this proved to be an infected hematoma.

Figure 37–37. Abscess (arrows) in the gallbladder fossa following laparoscopic cholecystectomy.

Cystic Duct Remnant. After cholecystectomy, a small remnant of the cystic duct remains in place. Rarely, patients may develop symptoms because of the residual cystic duct that mimic symptoms of cholecystitis or cholelithiasis (Fig. 37–38).⁸⁷ The remnant itself can enlarge over time and may function as a gallbladder, developing similar diseases such as gallstones and even carcinoma (Fig. 37–39).¹⁹²

Gallstones

The appearance of gallstones on CT depends on the complex relationship of several factors. The major determinant of appearance is the composition of the stone. Gallstones may be composed of, in general, three components: bile pigments, cholesterol, and calcium. Pure cholesterol or pure bile pigment stones are rare. Pure cholesterol stones will have a low density compared with bile (~100 HU in vitro).⁷⁵ Most stones, however, are a mixture of calcium, bile pigment, and cholesterol. The density of the mixed stone will vary, depending on the amount of each component present. There is some controversy in the literature as

Figure 37–38. Retained stone within cystic duct remnant (arrow).

Figure 37-39. Dilated cystic duct remnant (*large arrow*) containing dense stone (*arrowhead*).

Figure 37-41. Gallbladder containing rim of calcified stone with central gas (*short white arrow*) and relatively lucent stone (*black arrow*), with coarse calcified plaque (*long white arrow*) in gallbladder wall (porcelain gallbladder).

to whether calcium or cholesterol plays the predominant role in determining stone density on CT.^{14, 17, 18, 30, 33, 242} In general, calcium content is responsible for increasing the density of the stone. Up to 60% of gallstones demonstrate calcium on CT scan in vivo and are dense.^{11, 33} Other mixed-composition stones with less calcium may have a

density equal to bile and may be difficult to visualize on CT (Figs. 37-40 to 37-47).^{11, 13, 21, 75}

The pattern in which the components of the stone are distributed will affect the appearance of the stone. Calcium bilirubinate stones are often homogeneously dense (see

Figure 37-40. A, Small calcified stone in area of neck of gallbladder. B, Small calcified gallstone, adherent to anterior wall of gallbladder. C, Single stone with gas, which would be invisible without presence of gas.

Figure 37-42. Multiple laminated stones, with subtle internal pattern.

Fig. 37-39). Mixed-composition stones may have several patterns, depending on the distribution of calcium. They may have a dense rim of calcium peripherally with a low-density cholesterol center (see Figs. 37-41 and 37-42). They may also have a laminated appearance with alternating layers of calcification. Also, these stones may have punctate foci of increased density scattered throughout.

Stones may also have clefts centrally in their matrix that contain gas (see Figs. 37-41 and 37-43). Gas in these clefts appears as low-density fissures in various patterns, giving the so-called Mercedes-Benz sign, crow's feet sign, or seagull sign. Gas probably forms after shrinkage of the stone matrix.⁷⁵ The gas consists mostly of nitrogen. The significance of the gas clefts is little if any, except that it may contribute to floating of gallstones and it may aid in detecting stones on CT that are otherwise isodense with bile (see Fig. 37-44).

The ability of CT to detect gallstones depends on several factors, including stone composition, size, number, shape, bile density, and scanning technique. There have been numerous reports of varying degrees of sensitivity of CT

Figure 37-43. Multiple small lucent stones floating in gallbladder presenting as negative filling defects owing to contrast medium in gallbladder after ERCP.

Figure 37-44. Gas centrally in gallstones (arrows). These isodense stones would not be visible without the gas.

for detecting stones ranging from 78% to 83%.^{11, 13, 30, 33, 98, 106, 226} Uchida²²⁶ reported a 100% sensitivity for calcified stones. Havrilla reported a 78% sensitivity prospectively with a 94% sensitivity retrospectively.⁹⁸ The stone composition greatly affects the detection rate. Calcified stones that are hyperdense will be seen more readily than will composite stones, which are isodense to bile (see Fig. 37-45). In addition, the presence of matrix gas will increase detection rate (see Fig. 37-44). The size of stones will also affect detection rate, with small stones being missed because of partial voluming. Large stones that completely fill the lumen may not be detected if they are isodense with bile (see Fig. 37-46). In addition, if there are multiple tiny stones, they may layer and mimic milk of calcium bile. The density of bile may also affect stone detection (see Fig. 37-5). If the bile density is increased, lower density stones will appear as negative filling defects whereas higher-density stones may be obscured (see Fig. 37-47). Oral cholangiographic agents have been used to increase the density of bile to improve CT detection rates of gallstones. Finally, the technique of the CT examination will determine detection rates of stones. High-resolution CT that is targeted to the gallbladder with thin collimation is recommended.¹⁴

In recent years, a large volume of literature has considered the use of CT in selecting patients for nonsurgical therapy of gallstones. The nonsurgical options include extracorporeal shock-wave lithotripsy (ESWL), direct-contact dissolution with methyl tert-butyl ether (MTBE), and oral agents (cheno- and ursodeoxycholic acid). In the past, plain film was used to detect gallstones containing calcium, which precluded nonsurgical therapy. The problem is that 14% of patients with lucent stones based on plain films have pigment stones that are not candidates for dissolution. In addition, 33% of dense stones on plain film are cholesterol stones and would be candidates for nonsurgical therapy.¹⁴ Therefore, CT has been proposed as a more accurate method to evaluate which stones would be ideal for the nonsurgical therapies.

Studies have shown correlation between the CT attenuation of gallstones and the cholesterol and calcium content of the stone, and both in vitro and in vivo studies have

Figure 37-45. A, The gallbladder (G) is distended, but no filling defects are perceptible on this CT scan. B, Sagittal ultrasound scan through the gallbladder (G) demonstrates large, echogenic structures (arrow) within the gallbladder lumen, with associated acoustic shadowing (s) diagnostic of gallstones.

Figure 37-46. Enlarged gallbladder with thickened wall and large low-density stone in dependent portion.

Figure 37-47. Low-density gallstone (arrow) presents as negative filling defect because of high-density bile in gallbladder (G).

demonstrated this finding.^{8, 14, 30, 115, 243} Although there have been disagreements over whether it is the calcium or the cholesterol content that most determines the CT attenuation number, the basic finding is that the homogeneously dense stone with high attenuation numbers contains high levels of calcium and is a poor candidate for nonsurgical therapy. The less dense the stone, with lower attenuation values, the better the success with nonsurgical therapy. Unfortunately, the issue is not this straightforward. Concerning the success of dissolution, Baron and colleagues reported that the pattern of calcium within the stone may play a more important role than does simply the amount of calcium.¹⁸ For example, densely calcified stones do poorly with MTBE dissolution. However, if the calcium is arranged in lamina or a peripheral rim, the stone dissolves well. Those that dissolve best are isodense or hypodense with bile and contain a high amount of cholesterol. In addition, stones with a central nidus of calcium or peripheral rim of calcium have been shown to fragment with ESWL; these have now been approved for such therapy.³³ Therefore, success at nonsurgical treatment may not simply depend on the attenuation number of the stone but on multiple factors such as the pattern of calcification in the stone. CT may therefore be important in evaluating which patients will have the greatest success with the nonsurgical therapies; however, large-scale clinical trials will have to be performed.

Gallbladder Neoplasms

Gallbladder carcinoma is the most common malignant tumor of the gallbladder. Adenocarcinoma is the most common histologic type, in 90% of cases. Squamous carcinomas, mixed-type carcinomas, and sarcomas have been described in the gallbladder (Fig. 37-48).

Many benign neoplasms of the gallbladder have been reported such as a fibroma, lipoma, myxoma, granular cell tumor, leiomyoma, hemangioma, and neurofibroma.^{105, 159} The most common benign tumor of the gallbladder is the adenoma, which appears on CT as a small mass along the gallbladder wall.

Figure 37-48. Squamous cell carcinoma of the gallbladder (m).

Gallbladder carcinoma is the most common malignancy of the biliary tree and is the fifth most common gastrointestinal malignancy. Its peak occurrence is in the sixth decade or older, and there is a female predilection of 3-4:1.^{147, 204} The female predominance may be related to underlying inflammatory disease, and gallstones are detected in 65% to 95% of gallbladder carcinoma cases.^{147, 204} With new therapeutic methods for treating gallstones, such as lithotripsy or stone dissolution, that spare the gallbladder and leave it in place, surveillance of the gallbladder is recommended because of the increased risk of carcinoma.²⁰⁵ Calcification in the gallbladder wall (porcelain gallbladder) is associated with gallbladder carcinoma in 11% to 33% of cases (see Fig. 37-31).^{79, 106, 175} In addition, an increased risk of gallbladder carcinoma has been reported in patients with choledochal cysts.²⁴⁴

The clinical presentation of gallbladder carcinoma is often nonspecific and mimics other right upper quadrant diseases such as cholecystitis. Symptoms of jaundice and weight loss may not appear until the carcinoma has spread. Local extension of tumor is seen in 75% to 85% of patients at the time of presentation.¹⁴⁷ Therefore, a large portion of patients have tumors that are unresectable at presentation, and prognosis is poor, with a 5-year survival rate of less than 12% even if the carcinoma is incidentally detected.¹⁴⁷ An estimated 1% of gallbladder carcinoma is detected incidentally at the time of cholecystectomy.²³⁴

The appearance on CT is also nonspecific and often mimics benign disease. The typical findings of gallbladder carcinoma include three patterns: a mass replacing the gallbladder fossa, an intraluminal mass, and gallbladder wall thickening. The mass replacing the gallbladder fossa is the most common appearance in several series (Figs. 37-48 to 37-54).^{107, 111, 234, 242} Such a mass may contain gallstones within it and demonstrate central necrosis when large. A normal gallbladder cannot be detected (see Fig. 37-49). This form typically has invaded adjacent structures at the time of presentation. The thickened gallbladder wall type is less common but is very difficult to differentiate from benign cholecystitis (see Fig. 37-50). Kumar and Aggarwal¹³¹ reported a series of 50 cases and characterized the findings as follows. They divided their cases into two groups, group 1 in whom the gallbladder could be recog-

Figure 37-49. Gallbladder carcinoma spreading into the porta hepatis and head of pancreas.

nized and group 2 in whom the gallbladder could not be recognized. In group 1, the cases were further divided into type 1, mass filling the entire gallbladder lumen; type 2, a polypoidal mass projecting into the lumen; and type 3, an infiltrating tumor producing local or diffuse wall thickening. In 80% of cases the localized invasion into the adjacent liver was noted. The wall is usually 4 to 13 mm or greater in thickness, often asymmetrically thickened, and often nodular.¹⁰⁷ The intraluminal mass type is less common and presents as a polypoid mass in the gallbladder lumen (see Fig. 37-51). Lesions less than 10 mm in diameter are difficult to detect on CT.¹⁰⁶ Such lesions are difficult to differentiate from benign polyps or low-density adherent stones.

Associated findings on CT typically involve the spread of the tumor and aid in diagnosis. Gallbladder carcinoma most commonly spreads by direct invasion into adjacent structures, such as liver, porta hepatic structures, colon, duodenum, and pancreas. The liver is the most common

Figure 37-50. Thickening of the gallbladder wall from carcinoma. Local spread into the right lobe of the liver has occurred. Note blurring of adjacent liver margin. Without the spread to the liver, distinction from inflammatory thickening would be impossible.

Figure 37-51. Intraluminal gallbladder neoplasm eccentrically placed along the medial wall (*arrow*).

site of invasion in 34% to 89% of patients depending on the series, at the time of presentation.²⁰⁴ When the tumor invades the liver, the medial segment of the left lobe and the anterior segment of the right lobe are the most common targets (see Fig. 37-52). The area of invasion is usually hypodense relative to surrounding liver parenchyma on enhanced CT scan. Direct invasion of the liver versus simple contact of the tumor with the liver surface may be

Figure 37-53. Gallbladder carcinoma presenting as mass in the gallbladder fossa (m) with invasion into adjacent liver (*large arrows*) and duodenum (*small arrows*).

difficult to differentiate on CT. An irregular boundary with normal liver parenchyma suggests invasion (see Figs. 37-50 and 37-53).

Gallbladder carcinoma can metastasize to local nodes or distantly, primarily to the liver. Lymph nodes in the porta hepatis peripancreatic region and celiac axis may be involved. Engels reported that the foramen of Winslow

Figure 37-52. Gallbladder carcinoma developing over 1 year. A, Initial CT scan showing gallstones (*small arrows*) and nodular wall thickening (*large arrow*). B, One year later, CT scan shows mass in gallbladder fossa (m) with invasion into the liver (*arrows*). C, Associated biliary obstruction with dilated intrahepatic bile ducts (*arrows*).

lymph node and the superior pancreaticoduodenal node are the most frequent sites of nodal metastases (see Fig. 37-49).⁶⁷ Nodal masses may cause biliary obstruction and mimic a primary pancreatic tumor.²³⁴ Distant metastases to the liver appear as hypodense lesions relative to adjacent liver parenchyma on enhanced CT scans. Hepatic metastases are less common, however, than direct invasion.¹⁰⁶ Peritoneal carcinomatosis may occur.

Biliary obstruction is reported in 50% of cases of gallbladder carcinoma.¹⁴⁷ This may be due to direct invasion into the porta hepatis, obstructing lymphadenopathy, or intraductal spread of tumor. Intraductal spread of tumor was reported in only 4% of cases by Weiner and associates but is difficult to differentiate from cholangiocarcinoma (Figs. 37-52, 37-54, and 37-55); also see Figures 37-92 and 37-93.²³⁴

The differential diagnosis of gallbladder carcinoma on CT scan may be difficult. Gallbladder carcinoma often mimics cholecystitis (acute, chronic, and xanthogranulomatous), polyps, and occasionally adenomyomatosis (Fig. 37-56) radiographically and clinically. Findings common to both on CT include gallbladder wall thickening, gallstones, mass in the gallbladder fossa, edema in pericholecystic fat, and thickening of the hepatoduodenal ligament. A hypodense "halo" in the thickened gallbladder wall has been described as a helpful sign on CT of cholecystitis

Figure 37-54. Gallbladder carcinoma. A, Mass in gallbladder fossa (arrow). B, Intraductal spread of tumor throughout the biliary tree (arrows).

Figure 37-55. CT scan shows biopsy needle (curved arrow) in mass in central liver, representing gallbladder carcinoma from intrahepatic gallbladder. Note the faceted stone (arrow) surrounded by fluid in the central liver.

rather than carcinoma (see Fig. 37-19).²⁰⁴ The halo represents mural edema. Direct invasion into the liver suggests carcinoma; however, in rare cases, abscess formation may occur in liver parenchyma adjacent to gangrenous cholecystitis. Smathers and colleagues reported signs on CT that were helpful to differentiate gallbladder carcinoma from complicated cholecystitis including a mass less than half the size of the gallbladder, direct invasion of the liver with focal bulge of the anterior contour of the liver, biliary obstruction at the level of the porta hepatis, and lymphadenopathy.²⁰⁴

Primary malignant tumors of the liver may extend into the gallbladder fossa and mimic gallbladder carcinoma. Visualizing a normal gallbladder on CT, even if displaced by tumor, suggests a hepatic primary rather than gallbladder primary. Occasionally, the scirrhous type of gallbladder carcinoma may present as a contracted gallbladder with a thickened wall, mimicking a cholangiocarcinoma.¹⁴⁷

The diagnostic accuracy of CT scan with gallbladder carcinoma has been reported in several series. Itai reported successful detection of 27 of 30 cases of gallbladder carcinoma on CT for an accuracy of 90%.¹⁰⁶ In addition, CT and ultrasonography were compared by Weiner and associates and of 22 cases, ultrasonography detected 7 of 11 cases and CT detected 10 of 11 cases.²³⁴ The conclusion was that CT and ultrasonography were complementary.

Metastases

Metastases to the gallbladder are rare and often detected incidentally at autopsy. The most common primary malignancies with metastases reported to the gallbladder are pancreatic, gastric, renal cell, ovarian, and melanoma.^{28, 35, 147} Typically, metastases are focal nodular thickenings of the gallbladder wall and are often serosal in location. Such a finding in a patient with a known primary malignancy should raise the suspicion of gallbladder metastasis.

Figure 37-56. Adenomyomatosis presenting as a mass in the gallbladder fossa (m) and mimicking gallbladder carcinoma. (From Gerard PS, Berman D, Zafarnoss S: *J Comput Assist Tomogr* 14:490, 1990.)

The Biliary Tract

Normal Anatomy

Normal intrahepatic bile ducts (IHBDs) can be visualized in the liver parenchyma, especially on the newer-generation high-resolution CT scanners. In 40% of their patients, Liddell and colleagues reported seeing normal IHBDs as linear water density structures accompanying the portal vein branches peripherally in the liver parenchyma.¹³⁶ The normal IHBDs measure less than 3 mm, are few in number, and are randomly scattered throughout the liver. Such random scattering is a key observation, because visualization of IHBDs confluent with the hilum should raise suspicion of obstruction (Fig. 37-57). In addition, certain pathologic conditions may be difficult to differentiate from visualization of normal IHBDs. For example, sclerosing cholangitis and biliary obstruction in cirrhosis may present as a few, scattered, and small visible IHBDs (see Fig. 37-70A). The clinical setting will aid in differentiating these conditions. Finally, normal IHBDs are linear structures seen along one side of the portal vein. In contrast, periportal lymphedema will appear as low density

Figure 37-57. Mild intrahepatic biliary dilatation (arrows). Note the confluence of the ducts into the hilum.

accompanying the portal vein branches but will completely surround the portal vein and usually will be confluent with the hilum (Fig. 37-58).^{129, 233}

The normal IHBDs may lie on any side of the accompanying portal vein. As they course toward the hilum, the IHBDs from each lobe unite to form the right and left hepatic ducts, which have a constant location just anterior to the main portal vein bifurcation (Fig. 37-59A). The right and left hepatic ducts unite in the hilum to form the common hepatic duct (CHD). The CHD is usually imaged as a round or elliptical structure sitting anterior and often slightly lateral to the main portal vein (see Fig. 37-59B). On consecutive axial images, the CHD usually courses along a 40- to 45-degree oblique plane with reference to the midline sagittal plane (Fig. 37-59C and D).^{171, 172} It may, however, lie transversely; previously, this was considered a sign of obstruction and is now known to be an anatomic variant.^{89, 114} The CHD lies to the right and lateral to the proper hepatic artery. The right hepatic artery typically branches off the proper hepatic artery and passes between the CHD and main portal vein in 75% to 85% of patients.²³⁵ Contrast medium enhancement often aids in differentiating the water-density CHD from the enhanced hepatic artery and portal vein.

The common bile duct (CBD) forms when the cystic duct joins with the CHD. This union can occur at varying levels from high in the porta hepatis to near the ampulla of Vater. The confluence is rarely imaged on CT. The CBD enters the pancreas and typically lies along the posterior and lateral aspect of the pancreatic head. It can be used as a landmark to indicate the lateral border of the pancreatic head (see Fig. 37-59E).

The extrahepatic bile ducts (EHBDs: CHD and CBD) are readily visualized if the anatomy is recognized and the study tailored appropriately. Schulte and associates demonstrated the CHD in 66% of their patients and CBD in 82%.¹⁹⁹ The CHD usually measures 3 to 6 mm in short-axis diameter, and the CBD usually measures up to 8 mm.¹³ The diameter should be measured in short axis because the duct often courses obliquely through the axial image, making the long-axis diameter inaccurate.⁷⁴ In some patients, the CBD may be larger than 8 mm, and in postcholecystec-

Figure 37-58. Periportal edema. *A*, Edema around hilar portal vein branches (arrows). *B*, Edema forms lucent “collar” around portal vein branches (arrows). Note how low density completely surrounds the vein.

tomy patients it may measure up to 10 mm without obstruction.^{13, 51} The wall of the CHD and CBD can normally be visualized and measures less than 1.5 mm.¹⁹⁹ The wall may also enhance normally and be brighter than the adjacent pancreas (see Fig. 37-83*B*).

The CT examination should be tailored to examine the EHBDs. Narrow collimation of 4 to 5 mm at 5- to 10-mm intervals with bolus intravenous contrast agent enhancement injected at 1 to 2 mL/sec can be used. In addition, a small field of view should be used with the image targeted to the porta hepatis and pancreatic head (see Fig. 37-59). Oral cholangiographic agents have been used to demonstrate the biliary tree on CT scan^{89, 90}; however, these are probably not needed with the new higher-resolution scanners.

Congenital Biliary Anomalies

Biliary Atresia. In extrahepatic biliary atresia, ultrasonography and a DISIDA scan are typically the imaging studies performed initially to evaluate the biliary tree. Extrahepatic biliary atresia, however, is associated with other anomalies in 10% to 23% of patients.⁷⁸ Such anomalies include polysplenia, bilateral bilobed lungs, azygous continuation of the inferior vena cava, intestinal malrotation, and situs inversus.⁵⁷ CT can be used to demonstrate these associated anomalies. In addition, CT can be used to assess patients who, after corrective surgery, develop cholangitis, bile duct dilatation, bilomas, or intrahepatic calculi (see Fig. 37-96).⁵⁶ CT can also evaluate the development of cirrhosis, varices, splenomegaly, and ascites and play an important role in pre-liver transplant evaluation in such patients.

Choledochal Cyst. Congenital dilatation of the biliary tract, the so-called choledochal cyst, may occur and has been classified based on the spectrum of morphologic changes in the bile ducts.³⁴ The most common classification scheme of Alonso-Lej includes type I, which is dilatation of the CBD; type II, which is a diverticulum of the CBD; and type III, which is the rare choledochoceles. Type I has

been subdivided into cystic dilatation of the entire CBD and CHD, a small cyst of the distal CBD, or diffuse fusiform dilatation of the CBD. Todani and colleagues added to this classification type IV-A, representing multiple cysts of the IHBDs and EHBDs; type IV-B, representing multiple cysts of the EHBDs; and type V, representing multiple cysts of the IHBDs, or Caroli disease.^{196, 225} Placing a patient into a specific category is not as important to the patient's management as is describing the extent of involvement of the IHBDs and EHBDs.

The choledochal cyst is not truly a cyst of the biliary tract but rather some variation of duct dilatation. The etiology of this condition is not clear but may be multifactorial. Laing proposed that biliary atresia, neonatal hepatitis, and choledochal cyst are part of the same spectrum of disease.¹³² In addition, biliary atresia may be coexistent with choledochal cyst.²¹⁹ An anomalous union of the distal CBD and pancreatic duct has been reported in patients with a choledochal cyst; this may lead to pancreatic enzyme reflux into the CBD, causing dilatation. This anomalous union is seen in 10% to 58% of such patients.¹⁹⁶ The choledochoceles may have a different cause and may form as a result of obstruction at the ampulla with formation of a diverticulum of the sphincter, or it may represent a distal choledochal cyst that prolapses into the duodenum.

On CT, choledochal cyst can have varying appearances depending on the extent of ductal involvement and the degree of dilatation. There may only be mild EHBD dilatation (Fig. 37-60) or a large water-density mass in the porta hepatis or adjacent to the head of the pancreas (Fig. 37-61). Reportedly, 60% of patients with choledochal cyst will have associated congenital IHBD dilatation. This is usually limited to the central IHBDs.^{6, 239} Congenitally dilated IHBDs often have a lobulated cystic appearance with an abrupt transition zone at the junction with the normal ducts. Acquired biliary dilatation usually does not have the lobulated cystic appearance, and the dilated ducts usually taper gradually toward the periphery of the liver. With congenitally dilated ducts, the gallbladder is often normal. Direct communication of the cystic duct to the dilated EHBDs will aid in making the diagnosis of choledochal cyst, but this connection is often difficult to visualize on

Figure 37-59. Normal anatomy of extrahepatic bile duct. Branches of hepatic artery (small white arrows); small lymph nodes (n). *D*, Level 12 mm caudal to *C*. Common duct (c) is lateral to main portal vein (p) and posterolateral to the hepatic artery (small white arrow). *E*, Level 24 mm caudal to *D* at the level of the pancreatic head. Distal common duct (black arrow) lies in posterolateral aspect of pancreatic head (P). The descending duodenum (D) is filled with contrast medium just lateral to the pancreatic head. Superior mesenteric vein (p).

CT. Direct communication of nondilated ducts with the dilated portion is important to visualize and can be seen on CT unless the choledochal cyst is large. The differential diagnosis of choledochal cysts will include gastrointestinal tract duplication cysts, mesenteric cysts, hepatic cysts, pseudocysts, ovarian cyst, and a renal cyst.

Ultrasonography and CT can make the diagnosis if direct communication with the biliary tree and the choledochal cyst is demonstrated. Often this cannot be accomplished, and a DISIDA scan is required. CT cholangiography can be diagnostic and has been described revealing a contrast-fluid level within the choledochal cyst.²³⁹

Figure 37-60. Choledochal cyst. *A*, Dilatation of the extrahepatic common bile duct (c). *B*, Dilated common bile duct (c) down to the pancreatic head. No intrahepatic biliary dilatation is present.

The choledochocoele is typically seen as a round fluid-density structure in or medial to the pancreatic head, or it may lie completely within the lumen of the duodenum (Fig. 37-62). If an oral contrast agent has been given, the lesion may be circumscribed by the agent. The IHBDs and EHBDs are often not dilated. Differential diagnostic considerations would include an intraluminal duodenal diverticulum, small pseudocyst, duodenal duplication cyst, or small cystic neoplasm of the pancreas. CT cholangiography with administration of an oral cholangiographic agent may make the diagnosis.^{13, 53}

Most patients with choledochal cyst present with jaundice; therefore, imaging usually with CT or ultrasonography is performed. Only about 25% of patients present with the classic triad of pain, jaundice, and a right upper quadrant mass. Surgical correction is usually required and involves excision with a biliary-enteric anastomosis.

Complications of the choledochal cyst usually involve bile stasis with stone formation and infection, pancreatitis, biliary cirrhosis, and portal hypertension. There is, however, a reported increased incidence (4% to 28%) of malignancy involving the hepatobiliary system.^{6, 18, 86, 196, 244} The increased risk of malignancy is most likely caused by

chronic mucosal irritation, but it is not limited only to the choledochal cyst. Malignancy can develop anywhere in the biliary tree in such patients.²⁴⁴ CCA arising in the choledochal cyst will appear as a soft tissue density mass or irregular thickening of the cyst wall (see Fig. 37-98). Tumor arising in a choledochal cyst that was bypassed but not excised has been reported.²¹⁹ Gallbladder carcinoma has been reported in patients with a choledochal cyst and will appear as described previously in this chapter.

Caroli Disease. Caroli disease is also called communicating cavernous ectasis of the biliary tract. This is a rare disease that is part of the spectrum of congenital anomalies affecting the biliary tree and the kidney. The uncommon pure form of this entity involves congenital saccular dilatation of only the IHBDs. The second more common or "classic" form consists of the saccular bile duct dilatation with associated congenital hepatic fibrosis and portal hypertension.^{47, 195} In addition, there may be associated congenital dilatation of the EHBDs, suggesting that Caroli disease is part of the spectrum of choledochal cyst. Two thirds of such patients have been reported to have extrahepatic biliary abnormalities.¹⁹⁶ In addition, there is a high association with renal tubular ectasis and other renal cystic disease that may be part of the same underlying disorder.

On CT, the saccular cystic dilatation of the IHBDs may mimic multiple hepatic cysts. Several signs, however, aid in differentiating Caroli disease. Most importantly, the cystic areas often can be shown to communicate directly with the bile ducts.¹³ The distribution of cystic dilatation is often segmental. Finally, the "central dot sign" has been suggested as a pathognomonic sign of Caroli disease (Fig. 37-63).⁴⁷ This sign consists of cystic dilatation of the IHBDs with a small focus or "dot" of increased density lying apparently within the lumen of the duct. This "dot" represents the portal radicle, which has become engulfed by the dilating adjacent bile duct. The vessel is not truly in the lumen but is surrounded by the duct. The "dot" will enhance with intravenous contrast medium administration. One case report documented the "central dot sign" being seen with large hepatic cysts that occurred centrally in the

Figure 37-61. Large choledochal cyst (c).

Figure 37-62. A, Choledochocoele (arrow) appears as fluid density mass pushing laterally into barium-filled duodenum. B, Note common bile duct (small arrow) proximal to the choledochocoele is not dilated, nor is gallbladder distended (large arrow).

liver and most likely represented retention cysts in periductal glands.¹⁰¹

Complications of Caroli disease will include problems with bile stasis such as stone formation and cholangitis. In addition, pancreatitis, abscess formation, hepatic amyloidosis, and biliary malignancy have been associated with Caroli disease.^{102, 137} CT can document the extent of the disease and the presence of intrahepatic calculi, abscess formation, and so on. With congenital hepatic fibrosis, CT can document the presence of splenomegaly and varices. Finally, because of the association with renal cystic disease, the kidneys should be carefully evaluated for the presence of obvious cysts or calculi.

Cholangitis

Suppurative Cholangitis. Acute cholangitis is typically found in patients with obstruction or stone disease. Gram-negative organisms, such as *Escherichia coli*, are often responsible. The disease can become quite severe and

life-threatening, requiring immediate relief of the obstruction as well as antibiotic therapy.

On CT, dilatation of the IHBDs and EHBDs may be present unless early obstruction or partial obstruction is present.¹³ There may be increased density of the bile within the ducts because of purulent material (Fig. 37-64). The bile duct wall may be thickened concentrically and diffusely with prominent contrast agent enhancement (see Fig. 37-64).¹⁹⁹ High-resolution CT will best demonstrate this finding. Finally, gas-forming organisms can cause pneumobilia, which can be seen on CT especially in the nondependent portion of the biliary tract, typically in the left lobe.

CT can also be used to assess for complications of suppurative cholangitis, such as abscesses, which will appear as hypodense or fluid density areas adjacent to the bile ducts. Areas of liver parenchyma enhancement around the bile ducts may represent focal pyogenic hepatitis (see Fig. 37-68).⁴¹

AIDS Cholangitis. Several abnormalities in the biliary tract have been described in patients with AIDS. Although difficult to directly prove, the major cause of these biliary abnormalities is opportunistic infection, with the typical agents being *Cryptosporidium*, cytomegalovirus, *Mycobacterium avium-intracellulare*, *Candida albicans*, and *Klebsiella pneumoniae*.^{40, 188}

One of the most common biliary abnormalities is diffuse gallbladder wall thickening. This may be caused by edema in the gallbladder wall and can rapidly change over time. The exact cause of the wall edema is not clear but may be lymphatic obstruction, as has been shown in patients with adenopathy secondary to Kaposi's sarcoma or lymphoma.¹⁸⁸ The gallbladder wall thickening may also be caused by inflammation associated with acalculous cholecystitis. Both *Cryptosporidium* and cytomegalovirus have been implicated in causing acalculous cholecystitis in patients with AIDS.^{220, 221} The diagnosis may be difficult with imaging studies. However, if there is pericholecystic fluid or inflammatory changes on CT or ultrasonography, acalculous cholecystitis should be suspected in the appropriate clinical setting over noninflammatory gallbladder wall edema.

Figure 37-63. Caroli disease with cystic dilatation of the intrahepatic bile ducts. Arrows show "central dot sign." Air in ducts is caused by previous intervention. (Courtesy of R.L. Baron, M.D.)

Figure 37-64. A, Suppurative cholangitis with dilated intrahepatic ducts (black arrows) filled with dense inflammatory debris. Pneumobilia (white arrow) secondary to previous biliary enteric anastomosis. B, Suppurative cholangitis. Note thickened wall of the hepatic ducts (black arrows) and pneumobilia (white arrows).

Bile duct abnormalities in patients with AIDS can be arranged into two patterns. The first pattern involves narrowing only of the distal CBD; this may be due to acute papillitis or stricture and may mimic papillary stenosis.^{60, 220, 221} The remainder of the biliary tract in those cases may be dilated but otherwise normal. Acute inflammation or an inflammatory stricture of the distal CBD ampulla had been attributed to infection by *Cryptosporidium* and cytomegalovirus, both of which have been isolated on ampullary biopsy specimens.⁶⁰

The second pattern of bile duct abnormalities mimics primary sclerosing cholangitis (PSC) with multiple strictures occurring throughout the biliary tree with or without distal CBD/ampullary strictures (Fig. 37-65). Focal dilatation of the ducts and pruning of the intrahepatic ducts can occur as in PSC.⁶⁰ Thickening of the duct wall can be appreciated on CT or ultrasonography. The cause of these strictures has been linked to *Cryptosporidium* and cytomegalovirus.

Figure 37-65. AIDS cholangitis with dilated intrahepatic ducts (arrows). Note asymmetry of dilatation with greater dilatation of the left ducts. (From Dolmatch BL, Laing FC, Federle MP, et al: AIDS-related cholangitis: radiographic findings in nine patients. *Radiology* 163:313, 1987.)

AIDS patients with such biliary infections usually present with recurrent nonspecific abdominal pain, nausea, vomiting, fever, diarrhea, and cholestasis. Ultrasonography and CT can be performed to evaluate the biliary tract and rule out other abnormalities such as stone disease. The biliary abnormalities in AIDS patients may rapidly progress; therefore, ultrasonography and CT can be used for follow-up examinations.²²¹ ERCP is helpful in evaluating these patients by allowing for simultaneous ductal evaluation, biopsy, and papillotomy if required.

Parasitic Cholangitis. Parasitic infection of the biliary tract is rare in the United States. It is seen, however, in areas where there are large populations of immigrants particularly from Southeast Asia. *Clonorchis sinensis* and *Ascaris lumbricoides* are the two major biliary tract parasites.

Ascariasis can involve the biliary tract when the worms migrate through the ampulla. This may produce biliary colic, pyogenic cholangitis, and acalculous cholecystitis.¹⁸² Stones may form around the worms or ova, and ductal stricture formation may occur as a result of inflammatory reaction. Liver abscesses may develop secondary to infected and obstructed bile ducts. On CT, signs of cholangitis may be visualized with biliary dilatation, increased density of bile, pneumobilia, and parenchymal abscesses.¹⁸²

Clonorchiasis typically appears on CT scan as biliary dilatation. The degree of biliary dilatation will vary but is usually mild and involves only the IHBDs (Fig. 37-66). The EHBDs are characteristically not dilated. Dilatation of the IHBDs is caused by obstruction by the parasites or associated inflammatory debris. Thickening of the bile duct walls and the parasites themselves are usually not seen on CT but may be appreciated on ultrasonography.⁴⁵ CT may, however, demonstrate complications of the infection such as calculi, suppurative cholangitis, abscesses, or cholangiohepatitis. There is an increased incidence of CCA associated with chronic *Clonorchis* infection. If prominent biliary dilatation is seen, an underlying biliary neoplasm should be suspected because significant biliary dilatation is not common with *Clonorchis* infection alone.^{43, 45} Finally, CT

Figure 37-66. *Clonorchis* infection with dilated intrahepatic bile ducts (short arrows) and an intrahepatic cholangiocarcinoma (long arrows). (From Choi BI, Kim HJ, Han MC: CT findings of clonorchiasis. *AJR Am J Roentgenol* 152:281, 1989.)

may demonstrate an intrahepatic mass due to CCA (see Fig. 37-66).

Recurrent Pyogenic Cholangitis. Recurrent pyogenic cholangitis (RPC) or oriental cholangiohepatitis is a common disease in Asia and is being seen more in Western countries because of immigration. It is reported to be a very common cause of an acute abdomen requiring surgery in Southeast Asia.¹¹⁷ The disease involves recurrent episodes of infectious cholangitis that eventually leads to bile duct strictures, ductal obstruction, and biliary calculi. Clinically, the patients present with episodic abdominal pain, sepsis, and jaundice.

The findings on CT reflect the pathologic changes. There is usually significant intrahepatic and extrahepatic biliary dilatation. "Pruning" of the IHBDs can occur where there is notable dilatation of the duct, blunting of the peripheral end of the duct, and nonvisualization of the secondary duct branches. Debris and calculi are often seen within the ducts (Fig. 37-67). The stones are usually bile pigment stones with varying degrees of calcium content. Depending on the calcium content, the stones may vary from isodense to hyperdense with bile.^{13, 71} CT demonstrates the stones better than can ultrasonography, because often these stones are the consistency of paste and do not shadow on ultrasonography.^{71, 117, 186} In addition, pneumobilia is often present, which limits the ability to visualize the ducts optimally with ultrasound.

The IHBDs in the left lobe of the liver are usually the most common site of involvement and often the most severely involved.⁴¹ There may be diffuse areas of involvement in the liver with varying degrees of severity. However, solitary segmental involvement may occur. CT can demonstrate the areas of involvement quite well; this is important for surgical treatment planning.

Figure 37-67. Recurrent pyogenic cholangitis with significantly dilated intrahepatic bile ducts containing debris and stones (between arrows).

Periductal and duct wall enhancement can be seen on enhanced CT scans. This suggests acute inflammation (Fig. 37-68).⁴¹ In addition, periductal hepatic abscesses can be detected as a complication of acute episodes. Chronically, the disease can lead to lobar atrophy, cirrhosis, and portal hypertension.

The EHBD is often significantly dilated up to as much as 3 to 4 cm in diameter. The grossly distended common duct may be full of stones and debris, producing a cast of the duct (Fig. 37-69). This finding is very suggestive of RPC.¹¹⁷ On high-resolution CT, the wall of the common duct may be seen to be eccentrically and diffusely thickened.¹⁹⁹ Differential diagnosis of RPC includes PSC. However, the ducts are usually not as dilated in PSC and intrahepatic calculi are more common in RPC. Caroli's disease may be difficult to differentiate from RPC, but the extrahepatic bile duct is usually not as dilated in Caroli's disease.

Figure 37-68. Acute exacerbation of recurrent pyogenic cholangitis with dilated right intrahepatic bile ducts and periductal enhancement (arrows). (From Chan F, Man SW, Leong LL, Fan ST: Evaluation of recurrent pyogenic cholangitis with CT: Analysis of 50 patients. *Radiology* 170:165, 1989.)

Figure 37-69. Arrowheads show dilated common duct in the pancreatic head, filled with a calculus of higher attenuation than bile in the gallbladder (GB). (From Choi BI, Kim HJ, Han MC: CT findings of clonorchiasis. *Am J Roentgenol* 152:281, 1989.)

CT is probably the best examination for evaluating patients with RPC. Because the biliary tree in these patients is colonized with bacteria and parasites, biliary sepsis can occur from an invasive procedure such as ERCP and PTC. CT, however, will noninvasively demonstrate the distribution, extent, and severity of ductal and hepatic parenchymal involvement.

Sclerosing Cholangitis. Sclerosing cholangitis is a rare disease of the biliary tract that may be primary, in which case it is idiopathic, or associated with several diseases, such as ulcerative colitis, Crohn's disease, retroperitoneal fibrosis, and Reidel's stroma. It has been described in association with histiocytosis X, angioimmunoblastic lymphadenopathy, and AIDS.¹⁶⁸ Secondary sclerosing cholangitis can occur as a result of stone disease, previous biliary surgery, or recurrent infection, and these conditions must be excluded to diagnose PSC. The clinical course is insidious and manifested by intermittent jaundice. Cirrhosis may result because of chronic cholestasis.

The pathology of sclerosing cholangitis is characterized by ductal and periductal fibrosis causing focal strictures with alternating areas of ductal dilatation. This pattern produces the "beaded" appearance of the ducts on cholangiography. Classically, both the IHBDs and EHBDs are involved. However, cases have been reported of only the EHBDs being involved.⁴

The classically described findings of sclerosing cholangitis on CT reflect the cholangiographic and pathologic findings.^{4, 184, 217, 218} Randomly scattered, focal areas of bile duct dilatation are seen. The focally dilated ducts do not directly communicate, nor are they confluent with the hilum (Fig. 37-70A). There often is a segmental distribution to the involved ducts. The dilated ducts may demonstrate a beaded appearance reflecting alternating areas of strictures and dilatation. Pruning of the ducts may be seen where there is dilatation of the segmental ducts without dilatation of their secondary branches (see Fig. 37-70B).

Teefey and associates²¹⁸ reported a series of 100 patients in which pruning and beading of the IHBD was not specific for PSC but was also seen in infectious and malignant processes. Skip dilatations or areas of alternating stricture and duct dilatation were considered the strongest sign for PSC, especially in the absence of a mass or evidence of recurrent pyogenic cholangitis.

In PSC, the EHBD is often not dilated but may have a serpentine course. With high-resolution CT of the EHBD, subtle changes in the wall of the duct may be appreciated. Teefey and colleagues²¹⁷ described such findings in the EHBD, including wall thickening with enhancement, mural nodules, and focal ductal stenosis (see Fig. 37-70E).

The differential diagnosis of sclerosing cholangitis includes recurrent infectious cholangitis, diffuse sclerosing CCA, early Caroli's disease, ductal sclerosis after transcatheter arterial chemotherapy administration, and post-traumatic stricture.^{27, 174} The clinical setting may allow differentiation of several of these entities, but the CT appearances are often similar. Diffuse sclerosing CCA is difficult to differentiate and often requires a biopsy for the diagnosis. Brush biopsies of the ducts may not be helpful, because of the large component of fibrosis found in both PSC and sclerosing CCA. There is an increased incidence of CCA in sclerosing cholangitis, and sclerosing cholangitis is considered to be a premalignant condition.¹⁶⁵ In a series of patients receiving liver transplants for PSC, 10% of the patients were found to have CCA in their native livers.¹⁰⁰ Some of these cases were not discovered until later when the hepatectomy specimens were histologically examined. In sclerosing cholangitis, ductal dilatation is often not dramatic; this is caused by periductal fibrosis. However, if prominent duct dilatation, particularly segmental dilatation, is seen in a patient with known sclerosing cholangitis, or if ductal dilatation rapidly progresses, CCA should be suspected (see Fig. 37-70C).¹⁸⁷ Lymphadenopathy in the upper abdomen has been reported in PSC without CCA.¹⁶⁸ Such enlarged nodes often occur in the gastrohepatic ligament and in the pancreaticoduodenal chain. Lymphadenopathy in the porta hepatis has been reported as a sign suggesting a malignant biliary process (see Fig. 37-70D).¹⁸⁷ However, in PSC the mere presence of lymphadenopathy is not as useful. Therefore, biopsy of the lymph nodes may be required.

PTC and ERCP have been the gold standards for demonstrating sclerosing cholangitis. However, cholangiographically, ducts peripheral to tight strictures may not be filled adequately, and CT may show these areas better. In addition, given the possibility of underlying CCA, CT can evaluate for an extraductal mass or lymphadenopathy better than can cholangiography.

Biliary Obstruction

CT is often the initial examination performed in patients with clinical presentation of jaundice, or CT may be performed as a correlative examination after ultrasonography. The main goals of the CT examination are to determine the presence of obstruction, determine the level and extent of obstruction, and determine the cause. The overall accu-

Baron, MD.) *B*, Chronic sclerosing cholangitis with "pruning" of the left intrahepatic ducts (arrows) and atrophy of the right hepatic lobe. *C*, Sclerosing cholangitis with intrahepatic cholangiocarcinoma (large white arrows); scattered dilated intrahepatic ducts (small white arrows); biliary drainage catheter (black arrow). *D*, Same patient as in *C* with primary sclerosing and cholangiocarcinoma. Multiple metastatic lymph nodes (n). *E*, High-resolution CT of cholangitis with stricture of extrahepatic duct (black arrows) and enhancing mural nodules (white arrows). (From Teefey SA, Baron RL, Rohrmann CA, et al: Sclerosing cholangitis: CT findings. *Radiology* 169:635, 1988.)

racy of CT for diagnosing biliary obstruction has been reported at 85% to 97%.^{15, 134, 157, 224} The hallmark of biliary obstruction on CT is biliary dilatation (Figs. 37-71 to 37-77). Such intrahepatic dilatation appears as confluent linear structures of water density that course with the portal vein branches and gradually increase in size as they course toward the hilum. As mentioned previously, normal IHBDs may occasionally be visualized, but these are few in number, scattered, and not confluent (see Figs. 37-56 and 37-57). The dilated EHBD measures greater than 8 to 10 mm in short-axis measurement. With intravenous enhancement, dilated bile ducts can more easily be differentiated from enhancing vascular structures.

False negatives for biliary obstruction being diagnosed by CT do exist. For example, biliary dilatation may not be present in early obstruction. Animal studies have demonstrated that 4 days may be required before dilatation occurs after duct obstruction.¹³ In addition, obstruction may be present in certain cases without dilatation, as can happen in cirrhosis and in liver transplants.^{13, 132, 246} In such cases, cholangiography is required to make the diagnosis. In partial or intermittent obstruction, ductal dilatation may not be present. Choledocholithiasis has been reported to cause partial and intermittent obstruction without dilatation. A number of series have reported the lack of sensitivity of CT to detect obstruction in cases of distal common duct

Figure 37-71. Focal intrahepatic dilatation. *A*, Isolated intrahepatic biliary dilatation in the posterior segment of the right hepatic lobe because of focal stricture (arrow) secondary to stone disease and cholangitis. *B*, Focal intrahepatic biliary dilatation (arrows) due to breast carcinoma metastases.

D, Level just caudal to C shows abrupt termination of common duct with mass (arrow), which is the pancreatic carcinoma.

stones because of the lack of dilatation (Fig. 37-78).^{13, 55, 84, 85, 169} Finally, ductal dilatation, particularly intrahepatic, may be difficult to detect in the setting of diffuse fatty infiltration of the liver because of less contrast between the water-density ducts and the fatty liver (Fig. 37-79).¹⁷⁹

In CT, false positives for biliary dilatation, hence obstruction, do exist. Morehouse reported a case of metastatic pancreatic carcinoma extending along the portal vein branches mimicking biliary dilatation.¹⁵⁷ In addition, I have seen a case of a neurofibroma in the porta hepatis with extension along the portal vein branches mimicking biliary dilatation on ultrasonography, CT, and MRI (Fig. 37-80). Periductal tumor will often enhance and thereby be differentiated from dilated bile ducts. Periportal lymphedema and ascites tracking along the hepatoduodenal ligament may also mimic ductal dilatation (see Fig. 37-58). Finally, thrombosis of the portal vein can mimic dilated bile ducts.¹⁵⁷

In early obstruction and in some cases of prolonged obstruction, only extrahepatic biliary dilatation may be seen.^{16, 199, 202} This has been described with common bile duct stones. In postcholecystectomy patients, the EHBD is considered normal in size up to 10 mm in short-axis diame-

ter.^{13, 50, 161, 199} If there is any question of obstruction in such patients, a fatty meal challenge or intravenous cholecystokinase may be given with measurement of the EHBD before and 10 to 15 minutes after administration. A normal response is seen if the duct remains stable or decreases in diameter. If there is an increase in the size of the duct or onset of pain, the response is abnormal.¹³ Further evaluation of the duct with ERCP will be necessary.

Level and Extent of Obstruction. Depending on the series, the accuracy of CT for determining the level of obstruction has been reported to be 80% to 97%.^{15, 85, 171, 172} The dilated bile ducts can be traced on the same image or consecutive images to the transition point at which the caliber of the duct decreases or the duct disappears. This transition point is best demonstrated with thin-collimation axial images along the course of the biliary tree. Associated findings may aid in determining the level. Gallbladder dilatation can be seen with distal duct obstruction, but it is not a sensitive indicator and may be seen only in 50% of cases.¹⁶ Pancreatic duct dilatation points to an obstructing lesion in the distal common duct or even the ampulla (see Fig. 37-76).

Figure 37-76. High-resolution examination. Biliary obstruction secondary to pancreatic carcinoma with associated pancreatic duct dilatation (images obtained cephalad to A through E). A, Dilated intrahepatic bile ducts (arrows). B, Dilated common hepatic duct (C) near cystic duct confluence (large arrow), portal vein (p), hepatic artery (small arrows). C, Dilated common bile duct (C) and dilated pancreatic duct (arrows) indicate distal obstruction. Portal vein (p). D, Obstructing pancreatic carcinoma (m) compressing common bile duct (arrow). E, Pancreatic carcinoma (m) with totally occluded common bile duct.

The extent of the biliary tree that is obstructed can be determined by CT and can aid in therapy planning. For example, intrahepatic biliary obstruction proximal to the right or left hepatic duct is rarely amenable to surgical correction. Such obstruction is usually treated with percutaneous transhepatic catheter drainage. CT can demonstrate which dilated segmental ducts communicate and whether more than one catheter is required.¹⁸⁷ If the ducts in more than three segments are obstructed and do not communicate, these cases are poor candidates for surgery and catheter drainage. More distal EHBD obstruction is usually more amenable to surgical correction and percutaneous or endoscopic intervention.

Cause of Obstruction. The reported accuracy of CT for determining the cause of biliary obstruction ranges from 63% to 94%.^{15, 84, 85, 171, 172} The wide range of accuracies is most likely caused by different generations of CT scanners, different scanning techniques, and different types of pathology in each series. High-resolution scanning of the bile ducts with small field of view and thin collimation is the optimum technique (see Figs. 37-76 and 37-92). However, even with optimum technique, certain pathologic conditions such as cholesterol stones in the common duct are difficult to detect (see section on choledocholithiasis).

Differential diagnostic categories can be formulated based on the level at which obstruction occurs. Intrahepatic

Figure 37-77. Diagrammatic representation of cholangiographic and CT appearance of the bile duct in the most common lesions. (From Pedrosa CS, Casanova R, Lezana AH, Fernandez MC: Computed tomography in obstructive jaundice: II. The level of obstruction. *Radiology* 139:635, 1981.)

Figure 37-79. Biliary dilatation in a fatty liver. A, Postcontrast CT scan shows mild fatty infiltration of the liver with biliary dilatation (arrows). B, Five months after A, dilated bile ducts (arrows) are indistinguishable from the hypodense fatty liver on this postcontrast scan. (From Quint LE, Glazer GM: CT evaluation of the bile ducts in patients with fatty liver. *Radiology* 153:755, 1984.)

Figure 37-80. Peribiliary neurofibroma. *A*, Hypodense structures (arrows) mimicking dilated bile ducts are actually a neurofibroma branching along the biliary tract and portal structures. No dilated ducts were seen on ERCP. *B*, Hypodense neurofibroma (arrows) in the porta hepatis mimics dilated bile ducts.

ductal obstruction can be caused by strictures secondary to sclerosing cholangitis, infection, or neoplasm such as cholangiocarcinoma (see Fig. 37-72*A*). Rarely, metastases may cause intrahepatic ductal obstruction (see Fig. 37-72*B*). Christiansen reported focal dilatation of IHBDs limited to a subsegment in the posterior segment of the right hepatic lobe as a result of inadvertent ligation of an aberrant right hepatic duct during cholecystectomy.⁴⁹ At the hilum, obstruction is commonly a result of tumor such as CCA or a hepatic neoplasm extending into the hilum (see Figs. 37-88 to 37-90). In the suprapancreatic portion of the EHBD, strictures can be caused by benign disease such as sclerosing cholangitis, infectious cholangitis, surgery, or trauma. However, malignant strictures caused by CCA or secondary involvement by tumor of the gallbladder, pancreas, liver, or duodenum may occur (see Fig. 37-72). In addition, adenopathy secondary to inflammatory conditions or malignancy may obstruct the suprapancreatic duct (see Fig. 37-73). Finally, obstruction of the distal common duct can be a result of benign inflammatory strictures caused by cholangitis or pancreatitis, common duct stones, adenopathy, or tumor (pancreatic carcinoma or ampullary carcinoma) (see Figs. 37-74 to 37-76 and 37-81).

Once the level of obstruction is determined and various causes are considered, CT can be used to narrow the possibilities. A clue to the cause of obstruction is the manner in which the duct terminates at the site of obstruction (see Fig. 37-77). Different pathologic processes may have different appearances at the level of obstruction. Gradual tapering of the bile duct over a distance of 1 cm or greater is typically caused by benign disease, such as an inflammatory stricture (see Fig. 37-74). However, abrupt termination of the dilated bile duct over less than 5 mm is highly suggestive of malignancy, especially if seen in the suprapancreatic portion of the duct or near the ampulla (see Figs. 37-75 and 37-92). In a series by Reiman and colleagues abrupt termination of the suprapancreatic common duct was seen in all cases of malignancy but also in 50% of benign causes of obstruction.¹⁸⁷ Benign strictures occasionally may cause abrupt termination of the duct.¹³ In addition, obstructing cholesterol stones in the common

duct may cause abrupt termination of the duct and escape visualization because of its density being similar to bile (Figs. 37-82 and 37-83). However, if a soft tissue mass or lymphadenopathy is seen with the abrupt ductal termination, then malignancy should be suspected (see Fig. 37-92).^{84, 85, 187} CT is much better than cholangiography for demonstrating a mass outside the duct or periductal lymphadenopathy.

Schulte and colleagues described the appearance of the bile duct at or proximal to the level of obstruction as being helpful in determining the cause of obstruction.¹⁹⁹ High-resolution CT with thin collimation of images is optimum for this evaluation. Thickening of the duct wall (greater than 1.5 mm) can be observed and classified as concentric or eccentric and as focal or diffuse.¹⁹⁹ Focal concentric thickening in the distal common duct was nonspecific and attributed to stones, pancreatitis, or pancreatic carcinoma (see Fig. 37-83*B*). Diffuse concentric wall thickening was relatively specific and seen in infectious cholangitis (see Fig. 37-64*B*). Focal concentric or eccentric thickening else-

Figure 37-81. Homogeneously dense stone (arrow) in distal common bile duct on high-resolution axial image at level of uncinate process of pancreas.

Figure 37-82. Appearance of distal common bile duct seen on cholangiogram (left) and CT (right). 1, CT shows rounded duct with only water-density bile. 2, Target sign shows central, the stone, surrounded by water-density bile "halo" (see 4). 3, Crescent sign shows rim of water-density bile anterior to dependent stone (see 5). 4, Target sign can be seen when the image cuts through only one end of the stone. 5, Crescent sign can be seen when the stone does not fill the duct. 6, If stone is soft tissue density, no duct may be seen at this level, mimicking abrupt termination of the duct as if due to carcinoma. (From Baron RL: Computed tomography of the biliary tree. *Radiol Clin North Am* 29:1235, 1991.)

Figure 37-83. Common bile duct stones. A, Distal stone (arrow). Note "halo" of bile around stone. B, Level just cephalic to A. Normal size duct (arrows). Note enhancement in the wall of the duct relative to surrounding pancreas. C, Distal stone (arrows) of density similar to soft tissue. Note surrounding hypodense "halo" of bile. E, Cholesterol calculus in distal duct with low-density matrix and increased density rim along margin of stone (arrows).

where in the common duct may be seen in PSC, but this pattern may also be seen in CCA, especially with pronounced wall thickening (see Figs. 37-70E and 37-92).

Cholelithiasis. The diagnosis of common duct stones can be difficult to make on noninvasive imaging. Ultrasonography is often the first-line study requested to evaluate the patient with biliary colic or jaundice. Its reported sensitivity ranges up to 80% to 82%, but many series suggest lower sensitivity.¹⁶⁹ These studies are limited by the patient's body habitus, bowel gas, and experience of the operator. CT, on the other hand, is not limited by bowel gas or the patient's body habitus. The reported sensitivities of CT for choledocholithiasis vary but range up to 90%.^{12, 13, 15, 118, 172} The sensitivity of CT greatly depends on the type of stone in the duct and the technique of the examination. Although invasive, ERCP remains the gold standard technique for diagnosing common duct stones.

Strict attention to the technique of the CT examination will improve the ability to detect common duct stones. High-resolution CT should be performed with a small field of view targeted to the right upper quadrant with specific attention to the distal common duct. Thin collimation of axial images (3 to 5 mm thick) should be used with contiguous spacing at 3- to 5-mm intervals. Baron suggests that overlapping images are helpful in the distal common duct.¹² Intravenous contrast medium is helpful in defining structures in the porta hepatis. Contrast agent enhancement will aid in detecting subtle intrahepatic biliary dilatation and will also increase the visibility of the distal common duct contrasted to the pancreatic head. Oral administration of contrast medium may confuse the picture because dense contrast in the duodenum may obscure or mimic a calcified stone near the ampulla (Fig. 37-84). Therefore, studies should be performed without oral contrast agent administration. In addition, glucagon administered intravenously or intramuscularly will decrease artifact from bowel peristalsis. Finally, these examinations should be closely monitored so that they may be tailored to the individual patient.

Even given optimum scan technique, common duct

stones may elude detection because of the stone composition. Some stones are isodense with bile and may not be detected within the dilated common duct (see Fig. 37-82). Mixed-composition stones may have densities similar to soft tissue and may be difficult to detect when surrounded by pancreatic tissue. Calcium bilirubinate stones are the easiest to detect and appear as radiopaque calcified filling defects in the duct (see Figs. 37-81 and 37-83). However, calcium bilirubinate stones are the minority of stones (15% to 20%), with pure cholesterol and mixed-composition stones being the most common (80% to 85%). Secondary signs of common duct stones must be employed to detect these noncalcified stones.

The primary sign of a stone in the common duct is a radiopaque filling defect in the lumen (see Figs. 37-81 and 37-83). This sign may be detected even if the duct is not dilated (see Fig. 37-78). Common duct stones may not have associated biliary dilatation in 24% to 36% of cases even with obstruction.^{13, 54} Another sign, the target sign, consists of higher central density (the stone surrounded by a water-density "halo" of bile, which is surrounded by the duct wall (see Fig. 37-83). If the stone lies in the dependent portion of the duct, the surrounding bile will form a crescent of lower density anteriorly. Rarely, a papillary tumor may project into the lumen of the duct, giving a target sign and mimicking a stone (Fig. 37-85).

Secondary signs of duct stones include abrupt termination of the common duct without an associated mass. This sign, however, is not specific for stones and can be seen with obstructing malignancies, particularly pancreatic carcinoma. A second sign is a thin rim of increased density around a central portion of lower density (see Fig. 37-83E). The whole complex is thought to represent an impacted stone with the high-density rim representing a peripheral calcified layer in the stone. The density of the central portion will be hypodense or isodense with bile if the stone is composed of cholesterol, and soft tissue density if of mixed composition. It has been reported, however, that the thin dense rim represents the wall of the common duct and not part of the stone.¹³ There may be inflammation

Figure 37-84. Barium in duodenum (black arrow) mimics stones in distal common duct. White arrow shows barium and gas in descending duodenum.

Figure 37-85. Protrusion of pancreatic carcinoma into distal common duct (arrows) mimics soft tissue density stone. (From Baron RL: Computed tomography of the biliary tree. Radiol Clin North Am 29:1235, 1991.)

in the wall of the duct at the level of an impacted stone, which on high-resolution CT will show prominent contrast enhancement and concentric thickening.¹⁹⁹ A final secondary sign of a common duct stone is subtle soft tissue densities in the lumen of the duct; this may represent areas of different composition within the stone matrix (see Fig. 37-83D). Unfortunately, none of these secondary signs are specific for choledocholithiasis. Intraluminal neoplasm may demonstrate any of these signs. If there is an irregular termination to the dilated duct, visible mass, or lymphadenopathy, then neoplasm rather than a stone should be suspected. For calcified distal common duct stones, there are several false positives. Barium in the duodenum adjacent to the ampulla may mimic a common duct stone especially if the barium is within a duodenal diverticulum (see Fig. 37-84). Barium may reflux into the distal duct if there is a sphincterotomy or incompetent sphincter. In addition, a pancreatic duct stone or calcification in the pancreatic parenchyma may mimic a common duct stone. With high-resolution CT, most of these entities can be differentiated.

Intrahepatic Calculi. Intrahepatic biliary calculi are rare in Western countries. They typically occur in the setting of an underlying biliary abnormality such as congenital duct dilatation strictures, cholangitis, or previous biliary surgery.¹⁴⁷ They do occur in patients with biliary atresia status post portoenterostomy and in cystic fibrosis.⁶⁸ The density of the stones on CT depends on the amount of

calcium within the stone. CT, however, demonstrates the location of intrahepatic stones well and, unlike ultrasonography, is not inhibited by pneumobilia in visualizing these stones. (See section on recurrent pyogenic cholangitis).

Neoplasms of the Biliary Tree

Bile duct carcinoma or CCA is a rare malignancy comprising 0.5% to 1.0% of all malignancies.¹⁶⁴ It is much less common than the other hepatobiliary tumors, and much less common than hepatocellular or gallbladder carcinomas. The vast majority of bile duct malignancies are adenocarcinomas, but squamous carcinoma, carcinoid, leiomyosarcoma, and rhabdomyosarcoma of the bile ducts have been reported.^{76, 147, 224, 230} The peak age at onset for adenocarcinoma is usually in the sixth to seventh decade, although patients with predisposing inflammatory bowel disease or PSC may present earlier.¹⁴⁰ There is a slight male predominance (1.5:1.0), but this is not as great as with hepatocellular carcinoma.

The clinical presentation depends on where in the biliary tree the tumor arises. If the tumor arises intrahepatically, it usually presents late with abdominal pain. However, if the tumor arises in the hilum or the extrahepatic bile duct, presentation is usually earlier with painless jaundice.

There are a number of predisposing conditions for CCA, including inflammatory bowel disease (ulcerative colitis

Figure 37-86. Intrahepatic cholangiocarcinoma diagnosed in a patient with a malignant left pleural effusion. **A**, Hypodense mass relative to enhancing liver parenchyma with ill-defined margins (large arrows) and focal intrahepatic bile duct dilatation (small arrow). **B**, Delayed image approximately 15 minutes after initial contrast agent bolus shows persistent enhancement in the mass (arrows). **C**, Pronounced enhancement in the left hepatic lobe (L) during catheter injection of contrast medium directly into the celiac artery (arrow) in a patient with cholangiocarcinoma in left hepatic lobe. The abnormal enhancement pattern is caused by vascular invasion by the tumor.

and Crohn's disease), sclerosing cholangitis, *Clonorchis sinensis* infestation, biliary-enteric anastomosis, biliary tract stones and gallstones, Thoratrast exposure, choledochal cyst, Caroli's disease, congenital hepatic fibrosis, and pancreatocolic junction anomalies.^{43, 45, 65, 139, 147, 230} A case of CCA arising in a patient with cystic fibrosis has been reported.¹ Chronic inflammation of the bile ducts seems to be a common element leading to CCA. Sclerosing cholangitis with chronic biliary inflammation and fibrosis is most likely the underlying cause of an increased risk of CCA in patients with ulcerative colitis and Crohn's disease. Chronic inflammation is also probably the underlying cause of predisposition to CCA with chronic *Clonorchis* (liver fluke) infestation, stone disease, choledochal cyst, and biliary-enteric anastomoses.^{43, 45, 99, 155}

If CCA arises peripherally in the liver parenchyma from small IHBDs, it usually presents as a well-defined mass (Figs. 37–86 and 37–87; see also Fig. 37–93). Rarely, a diffusely infiltrating or sclerosing type can occur.¹⁶⁵ The mass is usually heterogeneous but hypodense relative to the liver on unenhanced scans. High-attenuation areas in the mass may be seen because of the presence of mucinous material.⁴⁷ These tumors can produce mucin, which may accumulate in adjacent bile ducts and, if dense, may mimic stones. Low-attenuation areas in the mass may be due to mucin or necrosis.¹⁰⁹ With intravenous contrast, heterogeneous enhancement is seen, often peripherally. The differential diagnostic considerations of such a mass would include hepatocellular carcinoma, biliary cystadenoma or cystadenocarcinoma, and metastases. Hepatocellular carcinoma is much more common than CCA and typically arises in cirrhotic livers. The serum α -fetoprotein is usually not elevated in CCA, but the bilirubin may be higher than typically seen with hepatocellular carcinoma.¹⁴⁷ In addition, if intrahepatic biliary dilatation is associated with the mass, then CCA should be suspected over hepatocellular carcinoma. Biliary cystadenoma and cystadenocarcinoma may mimic this form of CCA, but they are usually more cystic than is CCA. Finally, metastases may have a similar appearance to this form of CCA and are far more common (Fig. 37–88). Percutaneous needle biopsy is usually the only definite way to differentiate these lesions.

Figure 37–87. Mass (m) arising in liver with pathology revealing a mixed tumor containing cholangiocarcinoma and hepatoma. Note the density of the liver is increased because of previous Thoratrast administration.

Figure 37–88. Ill-defined mass in hilum of liver (large white arrows) causing biliary dilatation (small white arrows). The mass proved to be metastatic adenocarcinoma but mimicked cholangiocarcinoma.

CCA arising from the EHBDs is the most common form of this tumor. Grossly, the extrahepatic type of tumor is typically sclerosing and infiltrative, although it may be exophytic with an associated mass or polypoid with an intraluminal mass. The most common extrahepatic site is the confluence of the right and left hepatic ducts with the CHD. Such hilar CCA comprise up to 85% of extrahepatic CCA, depending on the series.^{12, 13, 230} A distinct pathologic variant of CCA found at the hilum is the so-called Klatskin tumor which spreads along the ducts with extensive fibrosis.⁶⁵ These infiltrating tumors are often difficult to visualize directly on CT scans because there may only be focal thickening of the duct wall and little associated mass (Fig. 37–89). A reported sensitivity of CT for such a hilar CCA has been reported in the range of only 40%.^{46, 240} The typical finding on CT is dilatation of the IHBDs in both the right and left lobes with nonunion of the dilated ducts at the hilum. Occasionally, a mass may be detected at the hilum, and it is typically hypodense relative to adjacent

Figure 37–89. Subtle infiltrative type of hilar cholangiocarcinoma presents as only mild thickening of the walls of the right and left hepatic ducts (arrows). Note dilated intrahepatic ducts.

Figure 37-90. Hilar cholangiocarcinoma (*large arrows*) presenting as a hypodense mass expanding out into the hepatic parenchyma. Because of the location of the tumor, intrahepatic biliary dilatation in both lobes of the liver occurs (*small arrows*).

liver parenchyma on enhanced scans (Fig. 37-90). Yamashita, however, reported a hypervascular densely enhancing exophytic-type mass as one appearance of hilar CCA.²⁴⁰ The density of the hypodense masses may increase relative to liver parenchyma on delayed scans (8 to 15 minutes post injection) (see Fig. 37-86).²¹⁴

CCA can arise elsewhere in the remainder of the EHBDs. Typically, these tumors are of the infiltrating type, with little detectable mass (Fig. 37-91). Biliary dilatation down to the level of the tumor will be present, and the appearance may mimic a benign stricture or obstruction secondary to a cholesterol stone. Thin-section CT targeted to this area, however, may reveal wall thickening or a small intraluminal mass consistent with tumor (Fig. 37-92).^{13, 199} CCA should be suspected if there is an abrupt end to the biliary dilatation without a visible mass, especially if it occurs between the hilum and the pancreatic head.¹³

Hilar CCA tends more to present early because of earlier

Figure 37-91. Infiltrative type of cholangiocarcinoma causing wall thickening of the common hepatic duct (*white arrows*); p = portal vein.

biliary obstruction than does the peripheral intrahepatic form of CCA. However, Thorsen and associates reported that in 57% of their patients with hilar CCA the tumors were nonresectable at presentation because of local liver invasion.²²⁴ Resectability depends on location of the tumor and local or distant metastasis. If there is extensive ductal involvement, liver or vascular invasion, or nodal involvement, resection is difficult. Generally, distal duct tumors tend to be more resectable than are proximal tumors. Proximal tumors invade locally with nodal metastases earlier than do distal tumors. Common sites for nodal metastases involve primarily the foramen of Winslow node, superior pancreaticoduodenal nodes, and posterior pancreaticoduodenal nodes (see Fig. 37-70D). Distant metastases to liver, lung, and bones may occur, but late in the disease. Portal vein invasion occurs less frequently with CCA than with hepatocellular carcinoma grossly (Fig. 37-93). However, microscopically, portal vein invasion is common (89% to 90%).²⁴¹ Enhancement of liver parenchyma peripheral to a CCA may be altered as a result of portal vein invasion. Increased enhancement of the liver parenchyma distal to the tumor on bolus-enhanced CT and decreased enhancement of the same area on CT arteriography has been described in the setting of portal vein invasion. The same area may appear hyperintense on T2-weighted MRI.¹¹¹

Lobar atrophy has been described with CCA, particularly hilar CCA (Fig. 37-94). The exact mechanism of lobar atrophy is not clear. One of the major causes is biliary obstruction, which secondarily leads to diversion of portal vein flow with resultant atrophy of the affected hepatic parenchyma.^{38, 213} Some have argued that lobar atrophy is a sign of nonresectability because it implies portal vein invasion.^{38, 230} However, others have demonstrated lobar atrophy with only biliary obstruction without venous involvement, and therefore these tumors are still resectable.¹⁸⁷ Lobar atrophy was once used as a sign of the presence of malignancy but also has been reported in benign biliary disease.

The staging of CCA is best performed by ultrasonography, CT, and cholangiography (PTC and ERCP) (Figs. 37-95 to 37-98). The overall accuracy of ultrasonography, CT, and cholangiography at staging CCA is reported at 70% to 90%.^{85, 164} Cholangiography demonstrates the extent of bile duct involvement better than do ultrasonography and CT especially for infiltrative tumors, and it provides a route for biopsy. MRI is gaining in its use for staging because of its sensitivity for vascular invasion and invasion into the hepatoduodenal ligament. Itoh compared ultrasonography, CT, and MRI for staging hilar or proximal bile duct carcinoma and concluded that CT was the best overall examination for tumor depiction but that MRI was more useful for evaluating portal vein invasion.¹¹² Nesbit and associates reported a 78% accuracy by CT for determining unresectability of CCA but only a 44% accuracy in suggesting resectability. False negatives were caused by metastases to lymph nodes and liver or portal vein invasion detected at surgery that were not detected by CT examination. Normal-sized positive lymph nodes and small hepatic metastases (<1 to 2 cm) may not be detected on CT.¹⁶⁴ Tailoring of the CT examination with thin-collimation axial images, bolus administration of intravenous contrast me-

dium, and a targeted small field of view will improve the ability to stage CCA.

Biliary Cystadenoma and Cystadenocarcinoma. The biliary cystadenoma and cystadenocarcinoma are rare neoplasms of the biliary tree. They typically arise from IHBDs but in rare cases are found in EHBDs. The vast majority arise in women and in patients older than 30 years of age. These lesions are usually large, well-defined, solitary masses that are multiloculated and hypodense relative to liver (Fig. 37-99).

Rarely, they may be multifocal.⁴⁴ There have been case

Figure 37-96. Patient with biliary atresia, cirrhosis, and porto-enterostomy. *A*, Multiple intrahepatic calculi (arrows). *B*, Cholangiogram revealing multiple filling defects consistent with stones (arrows).

reports of unilocular lesions, but most have multiple septations. The septations in the benign cystadenoma are usually thin, whereas those seen in the cystadenocarcinoma are often thicker with nodularity or papillary projections. These septations typically enhance on CT. Often, these

Figure 37-97. Intrahepatic biliary calculi (arrows) in patient with repeated episodes of cholangitis.

Figure 37-98. Cholangiocarcinoma arising in a choledochal cyst. The tumor presents as a focal thickening in the cyst wall (*arrow*). (From Baron RL: Computed tomography of the biliary tree. *Radiol Clin North Am* 29:1235, 1991.)

lesions contain mucin and are low in density. However, the cystic spaces may vary in density because of the presence of serous fluid, pus, or high amounts of cholesterol.³² They may communicate with the IHBDs and secrete mucinous material into the ducts. Calcifications may be present in the septations; when coarse and associated with nodular projections, they are more suggestive of cystadenocarcinoma.¹²⁸

The differential diagnosis of these lesions would include a complex benign cyst, abscess, hematoma, echinococcal cyst, mesenchymal hamartoma, undifferentiated embryonal sarcoma, and cystic metastases. Diagnosis has been performed with percutaneous biopsy.^{42, 104} Resection of these lesions is usually complete and leads to cure.

Other Neoplasms of the Biliary Tract. Other benign

Figure 37-99. Papillary cystadenocarcinoma appears as a multi-septated mass with areas of high and low density. Pneumobilia around mass (*arrows*) is secondary to recent biliary intervention.

neoplasms of the bile ducts are very rare. Papillomas, bile duct hamartomas, neurofibromas, and granular cell tumors have been reported (see Fig. 37-80).^{65, 66, 147} These lesions may appear as intraluminal filling defects or may simply occur with ductal obstruction. Cholangiography is typically most helpful at evaluating such lesions.

Lymphoma in the bile ducts has been described.²¹⁶ Typically, lymphomatous involvement of the biliary tract involves extrinsic compression by hepatoduodenal ligament and pancreaticoduodenal lymph nodes. Direct infiltration of the bile duct wall can occur, and it may cause biliary obstruction with a smooth structure. Only bile duct wall thickening may be seen without apparent mass on CT scan (Fig. 37-100).

Trauma to the Biliary Tree

Trauma to the gallbladder and biliary tree is uncommon and is almost always associated with hepatic injury.^{81, 206} Because of the location of the gallbladder, it is protected from injury to some degree by ribs and the liver. With blunt trauma, however, perforation, avulsion, or contusion of the gallbladder can occur in rare cases.

Perforation or laceration of the gallbladder is the most common type of injury and can result in bile leakage. Unfortunately, such leakage may not be detected for days to weeks.^{10, 56} On CT, ascites or a localized fluid collection around the gallbladder may be seen. The diagnosis can be made more accurately with aspiration of the fluid or a DISIDA scan.

A contusion of the gallbladder may simply appear as gallbladder wall thickening on CT, a nonspecific finding. Avulsion of the gallbladder is usually associated with bile ascites or hemoperitoneum on CT.¹¹⁶ Both conditions are difficult radiologic diagnoses.

Trauma to the bile ducts is usually associated with a hepatic injury. Bilomas may occur, particularly with perihepatic hepatic injuries.¹⁵⁰ Such bilomas may develop slowly over several days to weeks and may be asymptomatic. On CT, these bilomas will be focal collections of water density and may mimic abscesses or old hematomas. The diagnosis, however, can be made with DISIDA scans, aspiration, or cholangiography.

Hemobilia is a rare occurrence with hepatobiliary trauma but can result in increased density in the gallbladder or biliary tree on CT scan (Fig. 37-101). The differential diagnostic considerations for hemobilia include vicarious excretion of intravascular contrast agent, milk of calcium bile, or multiple small stones (see Figs. 37-4, 37-5, 37-8, 37-9, and 37-25).

Bilomas

Bilomas are focal collections of bile that may occur in a variety of locations such as intrahepatic, subcapsular, in the porta hepatis, and subhepatic (Fig. 37-102). Typically, they appear on CT as near water-density collections, although if infected or associated with hemorrhage, the density may be higher. Most bilomas occur after surgery, such as cholecystectomy or liver transplantation. However, they

Figure 37-100. Lymphoma involving wall of distal common bile duct. *A*, Pretreatment examination shows thickened tissue (arrows) around biliary stent. *B*, Post-treatment examination shows residual thickening of duct wall (arrows).

Figure 37-101. Hemobilia secondary to liver trauma. *A*, Hyperdense blood in central bile ducts (arrow). *B*, Hyperdense blood in gallbladder (arrow). H = liver hematoma.

can occur as a result of trauma particularly with blunt trauma to the gallbladder or with a penetrating laceration of the liver.^{81, 150} They may also occur iatrogenically after a liver biopsy. Bilomas may rarely occur after gallbladder perforation owing to severe acute cholecystitis; however, most pericholecystic fluid collections associated with acute cholecystitis are abscesses. Rare reports of spontaneous perforation of the CBD described bile leakage with biloma formation occurring spontaneously, particularly in children. The cause is not known but may be related to occult distal biliary obstruction or congenital weakness in the duct wall near the cystic duct and CBD junction.⁹⁵

CT cannot definitively diagnose a biloma, because it appears like other fluid collections. DISIDA scans or cholangiography better define leaks and bilomas. However, CT can be used to percutaneously aspirate or drain such collections.

Biliary Complications in Liver Transplants

Biliary complications after liver transplantation are the second most common cause of hepatic dysfunction after rejection and may occur in up to 20% of patients.^{167, 246–248} Biliary obstruction and bile leak are the two major categories of post-transplant biliary complications. Although cholangiography is the gold standard method for evaluating biliary complications, the clinical presentation of such problems is often nonspecific, and CT scans are initially obtained as general surveys of the abdomen. Therefore, recognition of the CT appearance of these biliary complications can aid in directing the work-up and therapy.

Bile leaks typically occur at the duct anastomosis. The preferred type of anastomosis is the duct-duct or choledochocholedochostomy, which preserves the recipient ampulla of Vater. If the recipient duct is diseased, as for example in recurrent cholangitis, then a biliary-enteric anastomosis or choledochojejunostomy is performed. In the latter case, a Roux loop of bowel is brought up into the porta hepatis and connected to the donor CBD. The Roux loop itself may be fluid-filled and mimic a fluid collection such as a biloma in the porta hepatis.⁹¹ Bile leaks will appear as focal fluid collections in the porta hepatis, or if nonfocal they may appear as ascites. Unfortunately, CT cannot differentiate bile from other fluid such as lymph, blood, or pus. A DISIDA scan or cholangiogram will be required to more definitively diagnose a bile leak. CT, however, can be used to percutaneously aspirate or drain such collections.

Bile leaks with associated bilomas can occur away from the anastomosis and should be recognized as a sign of a hepatic arterial complication, particularly thrombosis.²⁴⁵ In liver allografts, the biliary tree is highly dependent on the hepatic artery for its blood supply. Hepatic arterial occlusion results in bile duct necrosis with bile leak and biloma formation. Bilomas in the liver appear as focal fluid collections along the biliary tree (Fig. 37–103). They may or may not become infected. Hepatic infarcts may also be seen presenting as hypodense areas of liver parenchyma.

Biliary obstruction can occur because of strictures, occluded or trapped internal stent, T-tube dysfunction, com-

Figure 37–103. Liver transplant with hepatic arterial occlusion and resultant hepatic infarct (*large arrow*) and bile duct necrosis with formation of bilomas (*small arrows*).

mon duct redundancy, stones, or mucocele of the cystic duct.¹⁶⁷ A stricture at the biliary anastomosis is the most common cause of obstruction. Cholangiography is the best method for evaluating post-transplant biliary obstruction and can provide subsequent therapy via stenting or balloon dilatation. The hallmark of biliary obstruction on CT or ultrasonography is duct dilatation. However, in liver allografts, dilatation may not be present at the time that biliary obstruction is clinically suspected, and biliary obstruction may not be diagnosed by CT or ultrasonography.²⁴⁶ Cholangiography would be required in such cases. Obstructing stones or sludge may be recognized on CT as increased density in the bile ducts. In addition, a mucocele of the cystic duct remnant has been reported as a small round collection in the porta hepatis on CT.²⁴⁸ On cholangiography, it can be seen to compress the EHBD and cause obstruction. The differential diagnosis of such a small collection should include a seroma, abscess, pseudoaneurysm of the hepatic artery, hematoma, biloma, or Roux limb of the biliary-enteric anastomosis.

Diffuse dilatation of the EHBD after liver transplantation has been reported and may be seen with or without obstruction. This generalized dilatation of only the EHBD can occur gradually and may be caused by sphincter of Oddi dysfunction or denervation and devascularization of the duct during surgery.^{37, 149, 167, 247} Clinically, the patient may present with signs of biliary obstruction, or the dilatation may simply occur with no apparent obstruction to bile flow. If the degree of dilatation is significant, some element of obstruction should be suspected and further investigation with a DISIDA scan or cholangiography should be performed.

MRI of the Biliary Tract

Only a brief overview of MRI of the biliary tract will be provided here because currently it is not one of the primary imaging modalities of the biliary tract. Cholangiography, ultrasonography, and CT are more useful in evaluating the biliary tract. However, familiarity with the MR

Figure 37-104. Normal appearance of gallbladder on short TR (T1-weighted) image. Note hypointense signal of gallbladder (G). TR = 700; TE = 10.

appearance of the biliary tract and biliary diseases is essential when interpreting MRI examinations of the upper abdomen.

Bile has varying signal on MRI, depending on the fasting state of the individual, the pulse sequence used, and the presence of **pathology**.^{62, 103, 123, 124} In a fasting individual, bile is concentrated with little water content and increased concentrations of bile acids, cholesterol, and phospholipids. The T1 value of concentrated bile is shortened and on short TR/TE images (T1-weighted images) it can appear hyperintense compared with other body fluids such as cerebrospinal fluid.^{103, 123} On long TR/TE images (T2-weighted images), concentrated bile will still have high signal comparable to cerebrospinal fluid. In the nonfasting individual with rapid release of bile, concentration does not occur and the water content remains relatively high. Such bile behaves similar to other fluid such as cerebrospinal fluid with hypointensity on T1-weighted images and hyperintensity on T2-weighted images (Fig. 37-104). Layering of various

concentrations of bile can occur in the gallbladder. Because of a higher specific gravity, the more concentrated bile will layer dependently (Fig. 37-105).

Lack of concentrating ability of the gallbladder in fasting patients has been reported with acute cholecystitis.¹⁴⁴ Such patients demonstrate low signal intensity while on T1-weighted images rather than the high signal of concentrated bile. This finding in a fasting patient is suggestive of a concentrating problem in the gallbladder, as can be seen in acute cholecystitis. Unfortunately it is not a consistent finding in all cases of acute cholecystitis.^{124, 144, 236} In chronic cholecystitis, the concentrating function of the gallbladder is typically preserved so that the signal of bile is as expected in fasting and nonfasting patients.¹²⁴ Therefore, the signal characteristics of the gallbladder bile alone are not diagnostic for cholecystitis on MRI but must be used in conjunction with other signs such as gallbladder wall thickening, gallstones, and pericholecystic fluid.

Gallstones typically have no signal on MRI because of their solid nature, with little free water, rather than their chemical composition (Figs. 37-106 and 37-107).^{18, 156} There may, however, be retraction clefts centrally in the stone that contain fluid and appear hyperintense on T2-weighted images.⁹⁴ An atypical appearance of gallstones on MRI was reported where the stones demonstrated high signal on T1-weighted images because of high fatty acid content.¹⁵⁴

Carcinoma of the gallbladder has been described as a mass in the gallbladder fossa with hypointensity on T1-weighted images and hyperintensity on T2-weighted images relative to liver.^{191, 194, 238} Low signal gallstones may be seen within the gallbladder or engulfed within the mass. MRI is helpful in evaluating spread of tumor into the liver with hyperintensity of the tumor relative to liver parenchyma on T2-weighted images. In addition, MRI is reported to be more accurate than CT or ultrasonography for invasion of the hepatoduodenal ligament or spread to pancreaticoduodenal lymph nodes.¹⁹⁴ MRI performs as well as CT for direct spread to the liver and for hepatic metastases. The ability of MRI to detect small gallbladder tumors is not yet evident.

Figure 37-105. Layering bile in gallbladder. Note patient also has left renal neoplasm (m). A, T1-weighted image showing concentrated bile (hyperintense) layering dependently beneath the less concentrated bile (hypointense) in the gallbladder (white arrow). TR = 700; TE = 10. B, T2-weighted image showing all bile in gallbladder (G) turned hyperintense. TR = 2000; TE = 80.

Figure 37-106. Gallstones. *A*, Fat-suppression T1-weighted image showing gallbladder (*arrow*) with multiple tiny stones presenting as signal voids. *B*, T2-weighted image of same patient showing gallbladder (*large arrows*) and gallstones (*small arrow*).

Figure 37-107. Gallbladder carcinoma. *A*, CT scan showing mass (*M*) in gallbladder fossa. *B*, T1-weighted image showing hypointense mass (*M*) representing the gallbladder carcinoma. *C*, T1-weighted image of the same gallbladder carcinoma showing hypointense mass (*M*) with large gallstone (*s*) presenting as signal void.

Figure 37-108. T1-weighted image of subtle intrahepatic biliary dilatation (*arrows*). The dilated ducts are hyperintense because of the concentration of the bile. Adjacent vessels have relatively low signal. TR = 500; TE = 20.

Visualization of the IHBDs on MRI depends on the size of the ducts, concentration of the bile, pulse sequences used, motion artifact, and periportal high signal. Rapid pulse sequences, as in single breath-hold techniques, reduce respiratory and motion artifact and aid in evaluating the IHBDs, which are normally not visible. In our experience, T1- and T2-weighted sequences with fat suppression techniques are required for visualizing the IHBDs especially if they are only mildly dilated. Detecting mildly dilated IHBDs may still be difficult even with optimum imaging because the signal characteristics of bile will vary, depending on its concentration (Fig. 37-108). Signal contrast between the bile ducts and the liver therefore may be low, depending on the bile concentration. CT and ultrasonography are more sensitive for evaluating mild IHBD dilatation than is MRI.^{61, 94}

The EHBD can be visualized with varying normal diameters being reported (Fig. 37-109). The upper limit of normal size of the EHBD on T1-weighted images is 10 mm, and on T2-weighted images it is 11.8 mm.²¹¹ The distal CBD appears as a relatively hypointense round structure in the posterolateral portion of the pancreatic head on

Figure 37-109. Normal extrahepatic bile duct. A, Common hepatic duct (*arrow*) is hypointense on the T1-weighted image. Gallbladder (G); portal vein (p). TR = 578; TE = 15. B, T2-weighted image at level comparable to A. Common hepatic duct (*white arrow*) is now hyperintense. Gallbladder (G); portal vein (*black arrow*). TR = 1995; TE = 90. C, T1-weighted image of distal common bile duct (*arrow*) in pancreatic head also shows gallbladder (G) and duodenum (d). TR = 578; TE = 15. D, T2-weighted image at comparable level to C. Note distal common bile duct (*arrow*) now turns hyperintense. G = gallbladder; d = duodenum; TR = 1995; TE = 90.

Figure 37-110. Periportal high-signal intensity (arrows) seen around low-signal vessel centrally, in patient with liver disease. TR = 2000; TE = 80.

T1-weighted images and is relatively hyperintense on T2-weighted images.

The characteristics of several types of bile duct pathology on MRI have been described. The appearance of a choledochal cyst has been reported as a mass near the porta hepatis with a long T1 and T2 signal with associated biliary dilatation.^{3, 26} CCA has two basic appearances on MRI. Peripheral CCA often appears as a focal well-defined mass with homogeneous relatively high signal as compared with the liver on T2-weighted images. There may be a central scar and satellite nodules.^{70, 96} The detection rate of such tumors has been reported to be 78% to 100%.²¹⁵ This appearance, however, is not diagnostic for CCA, and other liver lesions such as hepatomas may have a similar appearance.^{70, 193} The second type of CCA is the more infiltrative and scirrhous type that may have relatively low signal on all sequences because of high fibrous tissue content.⁶² Biliary dilatation that abruptly terminates is an important sign for malignancy as on CT, ultrasonography,

and cholangiography. MRI is not as sensitive as CT for showing subtle duct wall thickening associated with CCA because of the lower spatial resolution and more artifacts. MRI, however, can demonstrate the hepatic lobar or segmental tumor location and detect intrahepatic metastases well. In addition, MRI may be quite useful at determining resectability.^{112, 201} It can demonstrate vascular invasion by showing loss of normal vascular flow void, tumor enhancement within the vessel, or abnormal signal in the liver parenchyma affected by the vascular invasion or occlusion.¹¹¹

Abnormal signal can be seen surrounding intrahepatic vascular structures and has been described by Matsui as periportal abnormal intensity.¹⁴² Periportal abnormal intensity is a nonspecific finding seen in diseases affecting the biliary tract, such as cholangitis, CCA, obstructive jaundice of any cause, and lymphedema secondary to malignant portal lymph nodes. Matsui reported that periportal abnormal intensity was not seen in cases of choledocholithiasis, pancreatic disease, or nonobstructive biliary dilatation.¹⁴² However, similar abnormal signal can be found in a variety of conditions including trauma, congestive heart failure, and rejection in liver allografts, and it has been described on CT as periportal lymphedema.^{7, 125, 129, 141, 233} Matsui reported that the periportal abnormal intensity represents edema, ductal proliferation, dilated lymphatics, and inflammatory infiltrates in periportal tissues.¹⁴² Typically, the periportal abnormal intensity is low signal on T1-weighted images and relatively high signal on T2-weighted images. It differs from biliary dilatation in that periportal abnormal intensity completely surrounds the portal vein, whereas dilated bile ducts are found on only one side of the vessel (Fig. 37-110).

Recently literature has been published concerning three-dimensional MR cholangiography. The technique employs two- and three-dimensional fast scanning sequences with multiplanar reconstruction so that the biliary tree can be visualized in three-dimensional projections (Figs. 37-111 and 37-112).¹⁵⁸ Such techniques will provide similar information as direct cholangiography, without the risks of an invasive procedure such as ERCP or PTC.

Figure 37-111. Gallbladder carcinoma invading liver. A, Invasion into liver appears as hypointense mass (M) on T1-weighted image. TR = 500; TE = 15. B, Tumor invasion into liver (M) becomes hyperintense on T2-weighted image. TR = 2357, TE = 80.

Figure 37-112. Biliary obstruction. A, T1-weighted image showing dilated intrahepatic bile ducts (arrows) of intermediate intensity; vessels have black signal void. TR = 500; TE = 20. B, Spin density T2-weighted image showing dilated ducts (short arrows) to have slightly higher signal than adjacent liver but lower signal than vessels (long arrows). TR = 2857, TE = 30. C, T2-weighted image showing dilated ducts to be hyperintense (short arrow) as are the vessels (long arrow). TR = 2571; TE = 80.

The Pancreas

John R. Haaga

During the past 25 years, the modern imaging techniques of computed tomography (CT) and magnetic resonance imaging (MRI) have made considerable improvement in the quality of life as well as in health care. A survey in the journal *Health Affairs* polled a group of 225 clinical physicians to determine what innovations they considered the most significant to the improvement and practice of medicine. An overwhelming number, 75%, responded that these two imaging modalities were the greatest innovations among many techniques and procedures, even including cancer treatments, angiographic stents, and cardiac bypass. The next closest innovation was angiotensin-converting enzyme inhibitors, which were regarded as the most important innovation in their practice by 54% of respondents.⁷²

This historical revolution is on the verge of being eclipsed by the newest methods of CT and MRI, especially multislice CT imaging. I noted in earlier editions of this book that prior to modern imaging techniques, the pancreas was a hidden organ. Early CT scanners afforded the first opportunities to actually visualize the exact anatomic characteristics of the pancreas and peripancreatic region. With the development of the spiral scanners, the diagnosis and treatment of pancreatic disease were no longer restricted by the lack of anatomic detail but rather by the inherent nature of the disease and the limitations of therapeutic regimens.

The development of multislice scanners and cone-beam multislice scanners ushers in a new age of medical diagnosis and treatment, the potential of which is almost unimaginable. These new tools provide the general anatomic information displayed by older scanners but with almost microscopic detail. The speed of imaging is so fast that temporal studies can be performed to assess physiologic function affected by molecular interactions. Although it is unlikely that such scanners will be used to visualize molecules themselves, they will indirectly permit assessment of molecular function.

This chapter discusses the normal anatomic appearance, relationships, and pathologic conditions of the pancreas as visualized by CT and MRI. The very latest information related to multislice scanners and cone-beam sources is included if available.

CT Anatomy

The pancreatic chapter in earlier editions of this book used multiple imaging modalities and artists' renditions to display anatomy and the routine axial, reconstructed images. The vascular images of modern imaging devices are so superior to these earlier images that few other

modalities are used in this chapter. It is truly a milestone event when even the classic drawings of Dr. Frank Netter are no longer needed to demonstrate relationships. The illustrations by Dr. Netter used in the first three editions of this book have been retired in favor of the new three-dimensional (3D) renderings now available with multislice scanners.

The pancreas is an exocrine and endocrine organ measuring approximately 15 cm in length and weighing 60 to 100 g. Its gross anatomic relationships with the stomach, duodenum, colon, and spleen are fairly constant, but individual variations do occur (Fig. 38-1). The pancreas is located in the anterior pararenal space of the retroperitoneum, just anterior to the perirenal (Gerota's) fascia and posterior to the parietal peritoneum (see Fig. 38-1). The uncinate portion of the pancreas (congenitally the ventral aspect of the pancreas) is in the inferior-most portion of the head of the pancreas, just posterior to the superior mesenteric artery and vein (Fig. 38-2A). The normal uncinate portion is triangular or wedge-shaped with the narrow portion beneath the superior mesenteric artery and vein (Fig. 38-2A). The head of the pancreas is medial and posterior to the bulb of the duodenum, bounded laterally by the second and inferiorly by the third portions of the duodenum (Fig. 38-2B). The neck of the pancreas is ante-

Figure 38-1. Reconstructed view from multislice scanner in 3D mode shows the general relationships of the pancreas (*curved arrow*) to adjacent structures such as the duodenum (D), stomach (S), spleen (SP), superior mesenteric artery (*short horizontal arrow*), and superior mesenteric vein (*long horizontal arrow*). One can also see without any special reconstruction techniques the pancreatic duct; data manipulation can even provide multiplanar views of the duct as well as internal endoscopic views.

Figure 38-2. See legend on opposite page

Figure 38-3. Arterial reconstruction of the vessels in the same patient correlates well with the axial slices. The splenic artery (*short vertical arrow*), common hepatic artery (*large curved arrow*), right and left hepatic arteries (*small curved arrows*), and gastroduodenal artery (*long horizontal arrow*) feeding the pancreaticoduodenal arcades are seen.

rior to the superior mesenteric artery and varies in thickness depending on the specific configuration (Fig. 38-2D and see Fig. 38-5). The tail and body of the pancreas lie immediately posterior to the fundus and antrum of the stomach (Fig. 38-2C and D). The omental bursa, or lesser peritoneal sac, is a potential space between the stomach and the pancreas that is never visualized unless it is filled with fluid. The entrance to this space, Winslow's foramen, is behind the free edge of the lesser omentum or the hepatoduodenal ligament, which contains the portal vein, common bile duct, and hepatic artery (Fig. 38-2C and D). The tail of the pancreas is adjacent to the hilum of the spleen, just anterior to the left adrenal gland, the upper pole of the left kidney, and the medial portion of the spleen. The tail usually tapers gradually in a constant plane, but occasionally it may be bulbous or angulated at the end.

The tail may also be closely adherent to the left kidney or surrounded by the peritoneum in unusual cases.

Vascular anatomy in and adjacent to the pancreas has always been well displayed with spiral scanners, but the vascular detail with the multislice scanners is nothing short of spectacular. With the thin slice images of multislice imaging, the overall vascular anatomy can be reconstructed to give a traditional angiographic representation (Fig. 38-3). The axial slices show remarkable clarity, so that not only the major vessels but also the very tiny branches and parenchymal feeding vessels can be seen. The major vessels such as the splenic, hepatic, and superior mesenteric arteries are obvious, but the third order of most vessels is seen. The gastroduodenal artery, pancreaticoduodenal arcade, transverse pancreatic artery, and parenchymal arteries are clearly depicted (Fig. 38-2). Calcifications occur com-

Figure 38-2. A, In most patients, the uncinate process (U) is wedge-shaped and extends behind the superior mesenteric artery as seen in this image. Small pancreatic artery (*curved arrow*) is seen on anterior surface of the pancreatic head, as are small unopacified vessels on the posterior surface of the pancreatic head (*vertical arrows*).

B, The head of the pancreas is posterior to the bulb and antrum (B) and medial to the second portion of the duodenum (D). This slightly higher scan in the same patient shows the confluence of the superior mesenteric vein (*short vertical arrow*) with the first portion of the portal vein just anterior to the superior mesenteric artery (*long vertical arrow*). The large pancreaticoduodenal artery (*horizontal arrow*) is just lateral to the pancreatic head. The distal end of the common bile duct is seen in the head of the pancreas (*curved arrow*).

C, Higher scan shows the confluence point between the head and the body of the pancreas. The *horizontal arrow* indicates the partially opacified portal vein as it courses toward the liver. The *vertical arrows* point to the gastroduodenal artery with its arcade branches lateral to the head of the pancreas; the larger medial vessels represent the gastroduodenal artery, whereas the more lateral branches are the beginning portions of the arcade.

D, Next scan in this sequence shows the main portion of the pancreatic body with the main duct. Small vessels are exquisitely displayed, including the tiny parenchymal vessel entering the anterior gland (*vertical arrow*) and portions of the transverse pancreatic artery behind the pancreas (*horizontal arrow*). The main pancreatic duct is in the gland; with multislice scanning, it is seen in almost every case. The two major vessels in the porta hepatis are the common hepatic artery (*large curved arrow*), and the small, more lateral arteries (*small curved arrows*) are the proper hepatic forming branches to the right and left lobes.

E, Higher scan shows most cephalad portion of the gland, with the main portion of the body and tail, adjacent to the spleen. The splenic artery (*horizontal arrow*) "overlies" the body, the main hepatic artery (*long curved arrow*), the right and left hepatic arteries (*small curved arrows*), the splenic vein (*small horizontal arrow*), and pancreatic duct (*large vertical arrow*).

F, Very highest scan shows the upper portion of the tail (*arrow*) adjacent to the splenic hilum.

Figure 38-4. This pancreas shows normal tapering of the tail and also a variation of density and texture very commonly seen. The gland shows discrete parenchymal lobules interspersed with fat. The pancreaticoduodenal artery (da), pancreaticoduodenal vein (dv), portal vein (p), splenic artery (a), and splenic vein (v) are noted adjacent to the body (B) and tail (T) of the gland. The splenic artery is usually quite tortuous, so only circular, cross-sectional portions are seen.

monly in the splenic artery and others and should not be mistaken for pancreatic calcifications.

The configuration and density of the pancreas may vary. There are several basic shapes; perhaps the most common is the gradually tapered pancreas in which the head is larger than either the body or the tail (Fig. 38-4). The narrowest portion is the neck, just anterior to the superior mesenteric artery. Another common variant is a dumbbell-shaped pancreas, which has a larger head and tail and a narrow neck immediately anterior to the superior mesenteric artery (Fig. 38-5). The tail of the pancreas may vary in its appearance, with the head being bulbous, angled, or especially close to the left kidney (Fig. 38-6). In some patients, in whom the peritoneal spaces have developed

Figure 38-5. Slightly different configuration of the normal gland is seen. Almost all portions of the gland, including the head (H), neck (N), body (B), and tail (T), are seen. This level of the gland has a "dumbbell" shape, in which the head (H) and body (B) are almost equal in size. Also seen are the common bile duct (b), splenic artery (curved arrow), and pancreatic arteries (arrowheads).

Figure 38-6. Variation of the tail (arrow) may be slightly bulbous and almost wraps around the kidney.

abnormally in utero, the splenic flexure of the colon may actually be posterior to the pancreas and within the hilum of the spleen; in such cases, the pancreatic tail and the spleen are partially peritonealized.

One should be familiar with these various configurations, because pathologic processes may on occasion mimic them (Figs. 38-7 through 38-9), and the only clue may be disproportion in the different portions of the gland. With the most common tapering configuration, there should be a gentle decrease in the size of the gland from the head to the tail. A pathologic process may cause the head to be normal and the rest to be atrophied (see later sections). If a dumbbell-shaped gland is present, the two ends should be about equal in size. If the head or body is larger than the other, a pathologic process should be considered.

The size of the normal pancreas may be measured several ways.^{34, 52} An average size or a range of sizes in the different regions of the pancreas can be used. The best anteroposterior measurements of the normal gland were made by Kreef and Sandin¹³⁹ as follows: head, 23 (± 3) mm; neck, 19 (± 2.5) mm; body, 20 (± 3) mm; and tail, 15 (± 2.5) mm. These measurements with CT differ from those with ultrasonography because ultrasonography is typ-

Figure 38-7. Scan shows a variation of the pancreatic tail in which the splenic flexure of the colon (arrow) is posterior to the tail of the pancreas. This variation implies incomplete fusion of the retroperitoneal fascia.

Figure 38-8. Pancreas with “short” body (B) without tail.

ically better for visualization of the splenic vein and artery, and so accordingly the ultrasonographic measurements tend to be smaller. The most accurate and noteworthy study of pancreatic size was performed by Muranaka and colleagues,¹⁸² who studied the anteroposterior diameter of the head and body in various age groups. They reconfirmed the observations by others that the size of the gland decreases with age, but the ratio of the head to the body remains almost constant.

Little attention was given to the craniocaudal measurement of the gland until the description of pancreas divisum, as described later. The first to measure the maximal craniocaudal dimension were Pochhammer and associates.²⁰⁵ They found that the mean length in women was 5.9 cm, with a range of 4.2 to 7.8 cm; the mean length in men was 6.2 cm, with a range of 4.8 to 7.6 cm. These measurements were made from older scanning devices, so the upper

value limits are probably greater than they should be; later measurements have been made in conjunction with diagnosis of pancreas divisum (see later).

The main pancreatic duct—Wirsung’s duct—runs the length of the pancreas and joins the common bile duct at Vater’s ampulle (Fig. 38-10). The accessory pancreatic duct—Santorini’s duct—is in the upper portion of the pancreas and is more horizontal than Wirsung’s duct (Figs. 38-2D to F and 38-11). The common bile duct travels with the portal vein and hepatic artery in the edge of the lesser omentum or the hepatoduodenal ligament. The common bile duct appears as a low-density structure in the posterior portion of the head of the pancreas (see Fig. 38-2C). It and the normal pancreatic duct are seen during rapid injection of intravenous contrast material as described in the technique section. Although both of these ducts are commonly visualized, their clear delineation is also variable.

The density or attenuation of the pancreas is normally the same as that of soft tissue, or somewhere between 30 and 50 HU, depending on whether contrast material has been administered. The normal pancreas increases in density after intravenous administration of urographic contrast material; the more rapid the administration (i.e., dynamic), the denser the enhancement.^{138, 164} If a bolus injection is administered, normal enhancement can be visualized during arterial, capillary, and venous phases. This enhancement of the normal gland has become an important differential sign for excluding necrosis in pancreatitis (see later section on necrotizing pancreatitis). The margin of the pancreas may be smooth or somewhat irregular (see Fig. 38-4). In the normal gland, variable normal fat tissue may be present, either interspersed along the margin of the gland or within the glandular portions. The entire pancreas may be replaced by fat, and the patient may not have any clinical symptoms. Some pathologic conditions, however, produce infiltration of fat when atrophy of the gland occurs, such as cystic fibrosis.

Figure 38-9. A questionable mass can be seen in the head of the pancreas, on a spiral scan. B, Second scan shows, quite clearly, sharp delineation of the margins of the head, clear definition of the vascular margins, and the normal density of the head parenchyma. What was suspicious for a mass on an older spiral scanner is very definitely normal on a multislice scanner.

Figure 38-10. 3D Reconstruction of the pancreas, with a contour pathway, shows both major and minor pancreatic ducts as they converge and course toward the ampulla of Vater. The accessory duct (*vertical arrow*), also known as the duct of Santorini, is larger in this patient than the main duct (*lower curved arrow*), also known as the duct of Wirsung. The main duct (*upper curved arrow*) is seen in the tail.

The position of the pancreas may also vary. In most patients, the head is more caudad than the tail, and the tail is located adjacent to the hilum of the spleen. In some patients, the head and tail may be more horizontal and below the spleen, and in others, the tip of the tail may be high. In postnephrectomy cases or with agenesis of the kidney, the appropriate portion of the gland moves posteriorly to partially fill in the space vacated by the kidney. One should not mistake the soft tissue density of the retropositioned pancreas for recurrent tumor.

Pancreatic Vessels and Lymphatic Drainage

The vascular anatomy of the pancreas consists of arteries originating from the celiac and superior mesenteric arteries and veins that drain into the tributaries of the superior mesenteric and portal veins (see Figs. 38-2 and 38-3). The main arteries, consisting of the dorsal pancreatic, great pancreatic, transverse pancreatic, and pancreaticoduodenal branches, are almost always present, but the

origin, size, and type of collateral supply may vary. The draining veins are also constant in that they parallel the arteries, and they drain into the pancreaticoduodenal, superior mesenteric, splenic, or portal veins. Small circular structures representing these vessels may be seen in and around the pancreas, but specific identification may be difficult. When pathologic occlusion of any of these vessels occurs, collateral vessels may open and become visible. A vein that has been reported to do this consistently is the posterior pancreaticoduodenal vein, as noted later.

The lymphatic drainage of the pancreas parallels the venous drainage. Small lymph nodes around vessels and in the various ligaments are commonly seen, but if nodes are 10 mm or larger, one should suspect neoplasm.

Impact of Multislice Scanners

The impact of multislice scanners has yet to be felt, but many significant improvements will occur. With the high-resolution, high-speed scans, the anatomy is absolutely exquisite. There is perfect visualization of even the most subtle change in density or margin of structures. The small-

Figure 38-11. A, Embryologic evolution of the pancreas. This diagram shows the ventral and dorsal bud of the pancreas forming off the primitive gut. B, Dorsal and ventral pancreas evolves from the pancreatic buds. C, Without fusion of the dorsal and ventral pancreas, pancreas divisum develops. D, Normal fusion of the gland should result in atrophy of the accessory duct to the duodenum with maintenance of main duct patency. Compare this with a normal duct in Figure 38-10.

est vessels can be visualized, even the tiny ones entering the glandular parenchyma itself. The end result of this improvement is better definition of detail in both normal and abnormal conditions. In some cases, when an older spiral scan demonstrates a subtle variation in contour suggesting an early neoplasm, a multislice scan clarifies a spurious finding (see Fig. 38-9).

Furthermore, with the remarkably vivid anatomy and the multiplanar reconstructions, it is clear to see that in the near future, endoscopy will be completely replaced except for the interventional procedures (Fig. 38-12; see also Figs. 38-113 and 38-136). I expect further refinement of the associated techniques that will permit accurate assessment of normal and abnormal ducts and glandular function. It is quite clear that as further techniques using pharmacology are developed, the function of the gland, as reflected by

blood flow, will be assessed by hormonal stimulation or suppression.

Normal MRI of the Pancreas

The appearance of the normal gland on MRI depends partially on the specific pulsing sequence used, but the overall configuration and intensity appearances are consistent. As one can note in Figure 38-13, the gland, with its uniform texture and the adjacent blood vessels, is easily appreciated. The relationship of the splenic vessels, gastroduodenal vessels, common bile duct, and other structures is consistent. With either less than optimal signal characteristics or motion artifacts, the best approach is to identify the location of the splenic vein and then extrapolate from that structure. Considering the many pulsing sequences that

Figure 38-12. A. Multislice images permit accurate reconstructions as shown in this coronal image of the pancreas. The pancreatic duct is dilated but better characterization of the duct is difficult. B. Image shows navigational tools superimposed on the image, the arrow path will follow the dilated duct. C. Proximal duct shows dilatation but is smooth along the wall. D. At a more distal site in the duct, the sacculations and irregularities can be better appreciated in the wall.

Figure 38-13. Normal-appearing gland with various pulsing sequences; see MRI section for specific technique. *A*, Normal gland, T1 weighting out of phase, shows discrete gland with the neck portion (*vertical arrow*) and tail of gland (*horizontal arrow*). The portal vein (*large curved arrow*) is seen behind the head, and the common bile duct (*small curved arrow*) is seen. *B*, Same slice with in-phase T1. Note the change in the visualization in the margins of the organs. The neck (*vertical arrow*) and tail (*horizontal arrow*) are again seen. *C*, Appearance of the gland during T2-weighted sequences. Note the effects of the change in sequence on the delineation of the margins of organs. *D*, Lower axial slice in same patient shows segment of the uncinus portion (*horizontal arrow*) of the gland behind the superior mesenteric artery, with T1 weighting out of phase. The neck (*vertical arrow*) is again seen. *E*, Lower axial slice with T2 weighting in the region of the head; compare with *D*.

are now available, it is not possible to perform them all in every patient. The best two sequences that I have found are the standard spin-echo T1-weighted images, which give good anatomic detail with relatively high signal intensity. A variety of breath-holding “flash” images are now available that minimize patient motion (see section on MRI technique).

Embryology and Congenital Variants

Although the embryology of many organs is well known to most physicians, knowledge of pancreatic development

is less prevalent. In the early stages of the embryo, there are a dorsal and a ventral pancreas, which are located on opposite sides of the gut. When the rotation of the bowel occurs, the dorsal and ventral pancreas fuse into a single gland. The dorsal portion becomes the body and tail, and the ventral portion becomes the head and uncinus portion of the gland (see Figs. 38-2 and 38-4).

As one might anticipate, the outcome of these complex events is variable, and the final form of the gland has a wide spectrum of variation, including a prominence of the head in the approximate area of the fusion, agenesis of the dorsal or ventral portion, annular pancreas, pancreas

divisum, and left-sided pancreas.⁸⁵ Furthermore, this embryologic information explains the wide variation in the ductal system.¹⁶⁵

Ductal Variations

Before the refinements of CT, discussion of ductal anatomy and variation was not relevant. With the current high-resolution systems and spiral scanning systems, one should be aware of possible variations because of the consistent

visualization of the ductal systems during normal and pathologic states. The main pancreatic duct in the dorsal pancreas combines with the ventral component to form the main duct, Wirsung's duct, which enters through the main papilla and ampulla of Vater. In most instances, the minor duct, Santorini's duct, becomes atretic. If the accessory Santorini's duct stays patent, it enters by means of the minor papilla (see Fig. 38–11). The multislice scanners permit reconstruction and display of the normal pancreatic duct and subtle variations. Although no studies have been performed comparing reconstructions to endoscopic retro-

Figure 38–14. A, Reconstruction of pancreatic duct shows main duct throughout length of gland. B, Multiplanar reconstruction of the same duct system in a slightly oblique axial mode shows a duplication of the main duct, which was not suspected and is probably of no clinical significance.

grade cholangiopancreatography (ERCP), it is very probable that ductograms by CT or MRI will replace routine diagnostic ERCP in the future (Fig. 38-14 and see Fig. 38-112).

Prominent Fusion Anomaly

One permutation of the variable anatomy is a prominent head of the pancreas at the junction point between the head and neck of the gland, close to the main portal vein. The contour of the gland may be so prominent that there may be a concern about an early neoplasm. Fortunately, with experience one can learn to identify this normal variant by carefully noting the density resulting from intravenous contrast enhancement and the appearance of the uncinate portion of the gland. With contrast enhancement, the density of the normal head is increased in a comparable amount relative to the adjacent gland. Virtually all non-islet cell tumors are hypovascular and show a lower density than normal, whereas most islet cell tumors are hypervascular and show an increase in density. Notwithstanding this information, the clinical suspicion may occasionally be so high that percutaneous biopsy is performed (see Chapter 61).

Pancreas Divisum

One of the most common anomalies is *pancreas divisum*, the nonfusion of the dorsal and ventral ductal system. Frequency by autopsy studies is reported between 4% and 14%, whereas ERCP confirmation of this entity is stated to be between 1% and 7%. Normally, during the 8 weeks of embryologic life, fusion of the ductal bud occurs to form the adult system. When such fusion does not occur, two separate entry points through the major and minor papilla form, which are the exclusive ductal paths from the dorsal and ventral gland.

The mere presence of this problem is not in itself significant, but patients with it are considered at risk for pancreatitis in the dorsal portion because of frequent narrowing of the duct at the papilla. Such pancreatitis is recurring unless corrective action is taken to eliminate the narrowing.

Diagnosis of this entity is best made on ERCP, but CT findings may suggest the correct diagnosis.^{154, 233, 234} Two findings appear to be consistent among the various articles reporting on this topic: the increase in the craniocaudal length and the occasional presence of a fat cleft separating the dorsal and ventral elements. Soulen and others^{233, 234} reported a size variation of the pancreas in a group of 12 patients with pancreatic divisum. These researchers noted an increase in both the anteroposterior and the craniocaudal dimensions; in the anteroposterior size, they noted a measurement of 3.2 cm compared with 2.7 cm for normals, and in the craniocaudal size, a measurement of 5.4 cm in pancreas divisum compared with 4.4 cm in the normal gland. Lindstrom and Ihse¹⁵⁴ found that the craniocaudal length of the pancreatic head was 40% greater in patients with pancreas divisum than in normal patients. They found that the anteroposterior dimensions and the total volume of

Figure 38-15. Pancreas divisum, which shows a fat cleft separating the head (h) from the body (b). The superior mesenteric vessels (arrows) are noted within the cleft. This appearance was seen on all sections through the gland.

the gland did not vary between the two groups. Zeman and colleagues²⁷⁰ reported the occasional presence of the fat cleft separating the two segments (Fig. 38-15). An associated finding that is not specific is that the dorsal duct was visualized in a high percentage of cases, which incidentally was said to be normal; the ventral duct was infrequently seen.

With the occurrence of pancreatitis, secondary changes in the gland, such as focal enlargement, irregularity of the margins, and calcifications, can occur. These changes have been noted in the reports on pancreas divisum and have been recognized as sequelae of the inflammation rather than primary findings of the problem. One author believed that the increased anteroposterior size noted by Soulen and others^{233, 234} might have been due to inflammation. Gold and coworkers⁷⁹ reported a case of pseudocyst associated with pancreas divisum.

Annular Pancreas

When rotation of the embryologic analogues does not occur and fusion takes place, an annular pancreas results.¹⁸⁶ In such cases, the CT appearance suggests a mass in the head of the pancreas. Although most case reports have described these findings as false-positive cases for tumors, the prospective diagnosis should be possible with an adequate contrast enhancement, correlative studies, and clinical information (Fig. 38-16).

Agenesis of the Gland or Short Pancreas

Several case reports showing agenesis of the dorsal pancreas have been published under the topic of congenital short pancreas.^{93, 100} In these cases, the head of the pancreas is in a normal location, but the body and tail of the pancreas distal to the neck are absent (Fig. 38-17). Congenitally short pancreas has a high association with polysplenia and other gastrointestinal anomalies, such as partial situs inversus, common mesentery with or without malrotation, preduodenal portal vein, lobulation of the liver, agenesis of

Figure 38-16. A, MR pancreatogram in a patient with an annular pancreas. The pancreatic duct is very dilated owing to chronic pancreatitis. Note the cystic enlargement of the duct in the body and tail (*arrows*) as well as the massive dilatation of the duct in the head. The head of the pancreas circumferentially surrounds the second portion of the duodenum (*curved arrow*). B, Axial image with true FISP sequencing, showing the dilated annular pancreatic duct (*arrows*), around the duodenum. C, Same image with T2 weighting. D, T1-weighted image obtained after instillation of gadolinium shows cystic duct and vascular enhancement. Courtesy of Elmer Merkel, University Hospitals of Cleveland.

Figure 38-17. A, Congenitally short pancreas or agenesis of the dorsal gland. This level shows the head of the gland (*black arrow*) behind the stomach. Note the preduodenal portal vein (*short arrow*). B, A higher section through the gland shows absence of the gland in the body and tail (*white arrow*). The preduodenal portal vein (*short arrow*) is again seen.

the gallbladder, biliary atresia, and absence of the omentum. The associated pancreatic anomalies reported include intraperitoneal location and annular shape. There has been a single case report of a carcinoma in such a case.

Ectopic Pancreas

The most common sites for ectopic pancreatic tissue are the esophagus, stomach, duodenum, jejunum, and Meckel's diverticulum. Ectopic tissue can produce a mass in such areas if the primordial ductal system and acinar elements produce and retain excretions.

Other Variants

In some other variants, the configuration of the gland varies or confusion arises because of embryologic or pathologic changes that occur in the adjacent structures. Several problems occur that are associated with anomalous rotation of the bowel and formation of the peritoneum. The splenic flexure may reside between the tail of the pancreas and the spleen, with associated abnormal contour and size. When malrotation of the duodenum occurs, the third portion of the duodenum does not cross beneath the superior mesenteric artery and vein. Other authors¹⁸ have stated that a reversal of the position of the superior mesenteric vein and artery helps diagnose this entity (our cases did not show this finding).¹⁸⁷ There has been a single case report²²⁶ of a torsion of the tail of the pancreas, which probably occurred as a result of abnormal fusion of the peritoneum and retroperitoneum (Fig. 38-18).

Several unusual problems can produce the findings of a spurious mass.¹⁸⁴ In patients with severe scoliosis, the acute angulation of the body can distort the gland so its anteroposterior dimension may be increased because of "buckling." A spurious mass can also be produced by an enlarged caudate lobe of the liver (Fig. 38-19), accessory spleen, fluid-filled diverticulum, or benign lymph node enlargement.

Figure 38-19. This image shows the slightly higher-density spurious "mass" (M) in the head of the pancreas. The mass is the caudate lobe of the liver projecting down and effacing the normal gland.

General Indications and Selection of Imaging Studies

Since the advent of the modern imaging technologies ultrasonography, CT, and MRI, evaluation and controversy about the appropriate roles and selection of the different modalities have continued. These topics, however, represent "moving targets" because of the remarkable advances that continue at an unprecedented pace. In general terms, however, it has become apparent that some inherent limitations can now be identified related to speed of data acquisition, signal-to-noise limitations, and inherent properties of imaging various biologic tissues. These three modalities have their own advantages and disadvantages, which are discussed later, but it is now apparent that CT is emerging as the preeminent imaging modality for the pancreas.

Ultrasonography continues to improve, with progress in signal refinement such as harmonic imaging and sophisticated Doppler strategies. Of course, there is no radiation with ultrasonography, making it a very safe examination.

Figure 38-18. A, Large mass in the midabdomen (*open arrow*) that is adjacent to the spleen (*arrow*). The mass was the tail of the pancreas, which was edematous because of torsion of the gland. B, Angiogram shows a circular configuration of the splenic artery and a cutoff at the end. (From Sheflin JR, Lee CM, Kretschmar KA: Torsion of wandering spleen and distal pancreas. *AJR* 142:100; copyright by American Roentgen Ray Society, 1984.)

There still remain inherent problems with imaging deep anatomy in large patients, because for high resolution, high-megahertz transducers are required. Such high-megahertz systems are limited by penetration and interference from high selective surfaces, such as air, bone, and metal. On the other hand, when the anatomy is accessible, Doppler ultrasonography is far superior to either CT or ultrasonography for measurement of vascular flow or other vascular characteristics.

In superficial structures, ultrasonography is unparalleled for the definition of texture changes and anatomic detail, for example, in the thyroid or the ovaries. The importance of close proximity and high resolution can be best appreciated by looking at the detail provided by endoscopic ultrasonography; because of the close proximity of the pancreas to the duodenum, high-resolution devices can be used, and the detail is spectacular. Therefore, for the accurate routine evaluation of the pancreas, ultrasonography at this time takes a secondary role to CT.

The refinements in MRI have been spectacular in recent years. This modality has the advantages of no radiation and being very good in the definition of anatomy and display of tissue characteristics. Because of the sophisticated pulsing sequences now available, definition of deep anatomy is not a problem, although accurate detection of calcification and air still presents a problem. In a given case, calcification or gas can be problematic because MRI cannot accurately detect small amounts nor distinguish between the two because of the absence of mobile protons in either material. Gadolinium contrast material is, of course, necessary for the best quality of scanning, and fortunately, there is no cross-reactivity with the iodinated contrast agents used in CT; this adds an important alternative for imaging in patients with pancreatic disease in whom allergy precludes the possibility of a contrast-enhanced CT scan.

The greatest strength of MRI is the measurement and display of subtle tissue signal changes related to a T1- and T2-weighting and proton density. The new high-speed techniques permit rapid imaging of tissue signals, contrast enhancement, and fat suppression which are quite accurate for unusual tumors of the pancreas, such as mucinous tumors and endocrine tumors. Another useful quality has been the ability to use multiple planes in the assessment of anatomy. Because of these properties, MRI is the modality of choice for unusual pancreatic tumors or problem-solving in the pancreas.

CT with multislice technology is now the absolute mainstay of pancreatic diagnosis for actually the very same reasons originally identified for CT. Over the past 20 years, comparing the qualities of the different modalities was quite difficult because the pace of innovation, development, and refinement varied among the three modalities. At this time, the new developments in multislice CT have clearly shown that the remarkable qualities of CT will give it the technologic edge for a number of years to come.

CT has no limitations related to definition of anatomy and density measurements. Prior shortcomings related to speed of acquisition and 3D anatomy have been eliminated. Size of patient, location of anatomy, proximity or presence of calcium, air, or metal, and even some patient motion have no adverse effect on CT imaging. The issues related

to radiation dose have been minimized because of the new techniques and methods used to minimize radiation dose now implemented by manufacturers. These methods are based on direct measurements of photon flux during the scan with adjustments "on the fly" or through assessment of body size or diameter and adjustment of the dose.

The speed and definition of new CT scanners are so remarkable because true 3D imaging is possible. Because the imaging voxel is symmetrical, measuring less than 1 mm in all planes, axial and reconstructed images have identical resolution. The only real disadvantage of the new CT scanners is that intravenous contrast material is required for most examinations. The issues related to allergic reactions and renal function have been managed for many years so the real impact of this issue for the future is minimal.

General CT Technique

The technique for CT examination of the pancreas is straightforward but may vary depending on some unusual circumstances, anatomy, and the information sought. Most commonly, the patient is examined in the supine position, and a large amount of intravenous contrast material is administered.

Multislice Scanner

With the modern multislice scanners, the techniques for scanning are remarkably simplified because of the exquisite imaging detail. With the very small isotropic pixels and the ability to evaluate the anatomy in three dimensions, there are never any problems visualizing very thin fat planes, small vessels, overlapping intestinal loops, or unusual congenital variations. Authors for many years have recognized the theoretical benefit of isotropic data sets, but the multislice scanners now permit such data collection.¹⁹

For definitive evaluation of the pancreas, it is appropriate to administer oral and intravenous contrast material. The amount of intravenous contrast material required is much less than with older spiral devices. A single injection of 90 mL of contrast material is more than sufficient to scan and rescan the pancreas multiple times. For the best results, one can use a bolus tracking program, or a simple manual delay will suffice. For best visualization of subtle disease and possible arterial reconstruction, it is appropriate to use 3-mm-thick scans. If ductal disease is suspected, 1-mm sections should be performed.

The pancreatic area should be scanned in three phases—baseline, arterial, and venous—for the following reasons: The baseline scan is critical for the detection and accurate localization of any calcification, which is obviously important to diagnosing and differentiating ductal calculi, chronic pancreatitis, vascular aneurysms (to distinguish pseudoaneurysm from true aneurysm), tumor calcification, and chronic infections.

The arterial phase with reconstructions defines normal or abnormal vessels. This is important in tumors for evaluating the presence of aberrant vessels or encasement. Aberrant vessels or anomalies are important to guide surgical intervention. Encasement is critical to determine inopera-

bility. Increased vascular enhancement is common in primary endocrine tumor and metastatic disease of the pancreas. The passage of contrast material may be so rapid that such enhancement may not be visible during the later venous or equilibration phase. The venous phase is critical to assess the homogeneous enhancement of the normal glandular parenchyma in order to detect subtle low-density lesions, which can be produced by cancer or focal inflammation, as well as venous enhancement.

McNulty and associates¹⁷³ studied the effects of contrast-enhanced multiphasic imaging with the multidetector row helical CT on the visualization of the vasculature. In a group of 49 patients, 21 normal and 28 with cancer, they studied the visualization of the vessels and enhancement of the parenchyma. With multiple scanning sequences, they evaluated the arterial phase (AP), pancreatic parenchymal phase (PPP), and the portal venous phase (PVP). As one might expect, they found that maximum arterial enhancement was seen during the PPP and maximum venous enhancement in the PVP. The pancreatic adenocarcinoma was best seen in PPP and PVP. They recommended that the AP be reserved for patients in whom angiography was required. Unfortunately, this recommendation is less useful because one can reliably plan a technique to trigger only on the arterial phase, so refinement of the technique (excluding the AP) is difficult at this time. In the future further work on the bolus chasing or detection programs will permit selection of the contrast phases to permit scanning during the venous phase. Reliable scanning of the venous phase is important because numerous researchers have shown that small veins are excellent indicators of local spread of tumor and inoperability.^{257, 267}

Standard Spiral Scanner

Assuming that one has a traditional spiral scanner, the injection should be made through a moderate-sized needle with a rapid injection rate. In most centers, a loading dose of 25 to 55 mL is given immediately, followed by an infusion rate of 1 to 1.5 mL/second to a maximal accumulated dose of 150 to 200 mL. The amount of contrast material given must be varied according to the patient's clinical and renal status. When modern equipment with either cluster or spiral scanning is used, the pancreatic area is scanned over several minutes. If one does not have the luxury of a high-speed scanner, the contrast material should be given with a 50-mL loading dose followed by a constant infusion during the entire period of the scan; administration rates may need to be adjusted according to the scanning time. Appropriate amounts of intravenous contrast material are important to provide enhancement, which highlights and distinguishes tumors, vascular or avascular, and blood vessels, whether they are normal, neovascular, collaterals, or aneurysmal.¹³²

Because most of the studies are performed during the course of a general examination, the scan slices are typically contiguous 8-mm slices or spiral scans over the entire upper abdomen. In special cases, if one is aware of pancreatic disease and one wishes to optimize visualization of the pancreatic duct, thin sections of 4 or 2 mm may be used. One should be aware of two shortcomings with

these techniques, related to contrast material and radiation dosage. Because the thin sections require more time to cover the anatomy, the rate of contrast administration must be changed. Furthermore, because more x-ray output is required to make the images acceptable, the patient receives a higher radiation exposure.

It is also important to administer oral contrast material for opacification of the duodenum and the bowel. Although iodinated materials can be given, they are less palatable, and they stimulate peristalsis, which can produce a large number of artifacts. Dilute barium solutions are better accepted by patients because of the pleasant taste, and they seldom produce artifacts. With slow scanning devices or with iodinated oral contrast material, one should be careful to distinguish the contrast material from pancreatic calcification so as not to miss or overestimate calcifications.

On occasion, even with modern scanners, portions of the pancreatic tail or head may be difficult to visualize if there is a paucity of fat in the retroperitoneum in front of the gland with the patient in a supine position. In such cases, examining the patient in the decubitus position after the ingestion of oral contrast material is helpful. This particular technique is valuable because it eliminates three troublesome false-positive possibilities: (1) with contrast material gravitating into the antrum of the stomach and duodenum,^{88, 128, 185} those structures cannot be confused for masses in the head of the pancreas; (2) air in the fundus of the stomach eliminates the pseudomass that can be produced by the partial volume effect of the fluid-filled stomach fundus; and (3) the jejunum moves away from the body and tail of the pancreas, eliminating another pseudomass.

Scanning Parameters and Radiation Dose

This is a complicated time for discussing scanning parameters because a large number of older spiral scanning devices are still in common use but a rapid replacement of these devices with multislice technology is occurring. With either device, the same clinical principles are valid. One should tailor the scanning parameters to best visualize the disease being sought. In general, one should use thicker slices for general survey of the pancreatic area, but thin sections should be used for high resolution of ductal anatomy and disease.

Scanning parameters on the CT scanner must be appropriately planned according to whether the scan is being performed for a general survey of the abdomen or a specific examination of the pancreas. The same principles of physics and clinical judgment must be exercised with either the multislice devices or the standard spiral devices, except that the considerations are somewhat reversed. With the older spiral scanning devices, it is easier to perform thick slices because of limitations of the x-ray tube and longer scanning times. With those devices, one consciously makes the decision to use thin sections when specific high-resolution detail is required. The path of least resistance is to not perform thin sections routinely.

With the multislice device, the equipment is so powerful and fast that it is almost easier to perform thin sections of

1 mm or less on every patient. The path of least resistance is to scan everyone with such thin sections and to perform multiple repetitive scans over the pancreas routinely. The temptation to produce so many scans must be avoided, and the study planned rationally. If one does not routinely plan the approach for each patient, there is a great risk that patients will receive excessive radiation doses for no clinical benefit.

Using these guidelines ensures that excessive radiation dose will not be administered to patients. These issues can be addressed by both selection of the appropriate technique and technologic improvements provided by the vendors. With older CT scanners, the highest kilovoltage possible should be used combined with the lowest suitable milliamper-second (mAs) value. It is the responsibility of the radiologist, during the installation of equipment and software, to ensure the standard radiation exposure is set to appropriate levels. This is, of course, very important for children. With the newer scanners, the vendors have intro-

duced new hardware and software that permit dynamic adjustment of the radiation dose. It is estimated that new techniques reduce the radiation dose for a single scan by 30% to 50%.

I find it gratifying to note that vendors have unknowingly taken advice from the previous edition, in which I stated, "It would seem logical that commercial vendors would be more receptive to making devices that would permit adjustable doses either automatically (why not phototimed CT scans?) or manually to minimize the radiation dose to small patients and to ensure good quality scans in large patients."

MRI Technique

As for many other organ areas, MRI pulsing and scanning techniques for the pancreas vary significantly among the many groups reporting in the literature. The art and

Figure 38-20. Enhancement of pancreatic carcinoma. A, Reconstructed MR cholangiographic image (TR = 12000 msec, TE = 255 msec) shows distal obstruction of the common bile duct (*straight arrows*) and pancreatic duct (*curved arrow*) due to a pancreatic adenocarcinoma near the ampulla. T1-weighted gradient-echo images (TR = 155 msec, TE = 2.2 msec) taken before gadolinium chelate injection (B) and during the arterial phase of gadolinium enhancement (C) show enhancement of the tumor (*arrows*), which is less than that of normal pancreatic parenchyma. D, Photomicrograph shows extensive fibrosis (F) throughout the tumor, bordering normal pancreatic parenchyma (N). (From Johnson PT, Outwater EK: Pancreatic carcinoma versus chronic pancreatitis: Dynamic MR imaging. *Radiology* 212:213-218, 1999.)

science of MRI continue to evolve very rapidly, so one must constantly consult the current literature for the latest pulsing sequences. In our laboratory, the favored pulse sequences for optimal visualization of the pancreas are as follows (see Fig. 38–13):

After acquisition of multiplanar gradient-echo localizing images, the pancreas imaging protocol consists of the following breath-hold sequences. Sequences 2 through 4 are acquired either axially or parallel to the main pancreatic duct to depict the whole pancreas within one slice.

1. Multislice 2D HASTE (half-Fourier acquisition single-shot turbo spin echo) (TR [repetition time] = 4.4 msec, TE [echo time] = 90 msec, NEX = 1, FA = 130 degrees, ST = 6 mm, matrix = 176×256 , TA = 22 sec), scan orientation coronal.
2. Multislice turbo spin echo T2-weighted sequence (TR = 5130 msec, TE = 138 msec, NEX = 1, FA = 180 degrees, ST = 6 mm, matrix = 116×256 , TA = 26 sec).
3. Multislice 2D, in phase and out of phase, T1-weighted gradient-echo sequence (TR = 144 msec, TE = 2.7

and 5.3 msec, NEX = 1, FA = 70 degrees, ST = 6 mm, matrix = 119×256).

4. Contrast-enhanced fat-saturated (using chemical shift technique multislice 2D FLASH (fast low-angle shot) (TR = 152 msec, TE = 4.1 msec, NEX = 1, FA = 80 degrees, ST = 6 mm, matrix = 117×256 , TA = 17 sec), after IV administration of gadopentetate dimeglumine (0.5 mol/L; Multihance [Bracco]), 0.2 mL per kg of body weight; delay times are 20 seconds and 70 seconds after start of the contrast injection.

The administration of intravenous gadolinium is as important for accurate diagnosis with MRI as the use of iodinated contrast material is for accurate diagnosis with CT scanning. Johnson and Outwater¹²¹ demonstrated clearly, in their article on MRI of the pancreas, that both chronic pancreatitis and carcinoma produce decreased gadolinium enhancement (Figs. 38–20 and 38–21).

Pancreatic Disease Detected by MRI

MRI has been used extensively to study virtually all pancreatic disease. The consensus in the literature is that

Figure 38–21. Enhancement of chronic pancreatitis. T1-weighted gradient echo images (TR = 140 msec, TE = 2.5 msec) before gadolinium chelate injection (A), during the arterial phase of gadolinium enhancement (B), and during the portal venous phase of enhancement (C). There is lower than normal enhancement of the pancreatic parenchyma (arrows). D, Histologic photomicrograph shows the extensive fibrosis (F) throughout the chronic pancreatitis. (From Johnson PT, Outwater EK: Pancreatic carcinoma versus chronic pancreatitis: Dynamic MR imaging. *Radiology* 212:213–218, 1999.)

MRI remains a secondary tool for general evaluation of the pancreas but is the modality of choice for unusual pancreatic tumors.

The obvious advantages of MRI are several. The technique does not use ionizing radiation and has no proven ill effects from the magnetic fields or radiofrequency pulses. The contrast resolution of soft tissues is remarkable and shows subtle changes based on proton density, especially edema and relaxation times. This quality suits it well for detecting subtle tissue relaxation differences, enabling the optimal imaging of unusual tumors such as endocrine or cystic tumors.

The disadvantages of MRI are associated with consistency of image quality and difficulty with visualization of certain tissue components. Although in most cases the images of the pancreas and the immediate area are of good

quality, the spatial fidelity and image clarity still do not match those of CT scans. When fast pulse sequences are used to visualize anatomy, the signal-to-noise ratio can be compromised and the clarity of the images may be affected. Two tissue components, air and calcium, are important to detect and characterize for optimal diagnosis of pancreatic disease. Unfortunately, MRI is not reliable in displaying subtle collections of either component; in fact, air and calcium can be confused for each other on MRI.

MRI Pancreatography

In the last several years, the technique has been refined to a reliable method to visualize ductal anatomy and disease. Numerous authors have reported the consistent visual-

Figure 38-22. A, Pancreatic duct during endoscopic retrograde cholangiopancreatography (ERCP). B, MR cholangiopancreatogram (MRCP) showing acinar filling. (From Matos C, Deviere J, Cremer M, et al: Acinar filling during secretin-stimulated MR pancreatography. *AJR Am J Roentgenol* 171: 165-169, 1998.)

ization of normal duct and congenital variations. Manfredi and coworkers¹⁶³ reported a large series of patients evaluated by magnetic resonance cholangiopancreatography (MRCP) in which they successfully diagnosed 5 cases of pancreas divisum and three cases of santorinicele. Sica and colleagues²²⁹ found an excellent correlation between MRCP and ERCP. Furthermore, other authors have demonstrated the benefit of using MR pancreatography with secretin stimulation for assessment of exocrine function (Fig. 38-22).

Pancreatitis

Imaging of acute pancreatitis is possible with the newer sequences. Several authors, most recently Semelka and colleagues,²²⁴ have shown that the acute changes are quite consistently imaged with the new fast acquisition images.

The findings that can be noted include the overall morphology of the gland, presence of edema, enlargement of the pancreatic duct, formation of fluid collections, and presence of fibrotic tissue. Edema or fluid within the parenchyma shows as a decrease in intensity with T1-weighted images and an increase in intensity with T2-weighted im-

ages. The evolution of the disease, with either an increase in fluid during exacerbation or a decrease in fluid during improvement, can be seen (Figs. 38-23 and 38-24). The dilatation of the pancreatic duct is seen as a tubular fluid density structure within the gland. The signal intensity varies from bright to dark depending on weighting of the signal (see Fig. 38-23).

Piironen and associates²⁰² demonstrated in a swine model that hemorrhagic necrotizing pancreatitis could be demonstrated with turboflash imaging during the injection of gadolinium. These authors noted that the appearance was very similar to that noted with CT contrast studies and remarked that their findings encourage the use of MRI as an alternative for diagnosing necrotizing pancreatitis.

As the disease evolves, any pseudocyst is visualized as a fluid collection showing the appropriate signal intensity. T1-weighted images are dark (see Fig. 38-23A), and T2-weighted images are bright.

As chronic disease develops in the gland, fibrosis and calcification may occur. Fibrosis characteristically shows an absence of signal on both T1- and T2-weighted imaging. Kim and associates¹³⁰ and Johnson and Outwater¹²¹ demonstrated that fibrosis visible on MRI correlates with histologic findings. Furthermore, there is no reliable way to

Figure 38-23. Chronic pancreatitis with pseudocysts. *A*, ERCP shows dilatation of the pancreatic duct (arrow) with calcifications throughout the pancreas. No communication between the duct and pseudocyst is shown. *B*, Contrast-enhanced, 5-mm CT scan shows extensive calcification along the wall of the pancreatic duct and clearly shows the pseudocyst arising from the posterior aspect of the body of the pancreas. *C*, Gadolinium-enhanced fast spin echo (FSE) (TR = 500 msec, TE = 15 msec) MR image clearly shows that the pancreatic duct (arrow) is anterior to the pseudocyst. Dilated duct and calcification could not be clearly distinguished. (From Semelka RC, Kroeker MA, Shoenut JP, et al: Pancreatic disease: Prospective comparison of CT, ERCP, and 1.5-T MR imaging with dynamic gadolinium enhancement and fat suppression. *Radiology* 181:785-791, 1991.)

Figure 38-24. Chronic pancreatitis in a 32-year-old man. *A*, On a contrast-enhanced, 5-mm CT scan, calcifications in the pancreas and mild dilatation of the pancreatic duct (*arrow*) are well demonstrated. *B*, On a fast spin echo (FSE) (TR = 500 msec, TE = 15 msec) MR image, the pancreas is of uniformly low signal intensity, but the signal void calcifications are difficult to appreciate (*arrow*). *C*, On an immediate postcontrast FLASH MR image, contrast enhancement is diminished, and the pancreas enhances inhomogeneously with an irregular region of low signal intensity in the tail (*large arrow*). Mild ductal dilatation can be appreciated (*small arrow*). (From Semelka RC, Kroeker MA, Shoenut JP, et al: Pancreatic disease: Prospective comparison of CT, ERCP, and 1.5-T MR imaging with dynamic gadolinium enhancement and fat suppression. *Radiology* 181:785-791, 1991.)

differentiate such a finding from neoplasm (see Figs. 38-20 and 38-21).

Calcifications may show a signal void on all signals if the calcium is quite mature or a normal signal depending on the amount of hydration of the calcium (see Fig. 38-23*A* and *C*). All authors reporting note that the inability to detect and characterize calcium consistently is a definite disadvantage.

Cystic Fibrosis

MRI has been used to evaluate cystic fibrosis by numerous researchers. These authors have noted that because MRI visualizes fat well, patterns of change resulting from atrophic changes were well seen. Tham and associates²⁵² reported on 15 cases and noted three appearances: complete replacement of the gland by fat, resulting in a lobulated, enlarged gland; small atrophic gland with partial fat replacement; and diffuse atrophy of the gland.

Pancreatic Transplants

The ability of MRI to detect edema of the pancreas makes it well suited for evaluation of pancreatic transplants. The most notable article on this topic is by Yuh and colleagues.²⁶⁸ These authors noted that configuration and density changes related to edema and rejection can be well evaluated by MRI. They found that the progression and

regression of rejection could be followed by monitoring the increase and decrease in the amount of fluid within the gland. Chronic rejection showed as a progressive decrease in size as well as the decrease in signal associated with the development of fibrosis.

Another potential use of MRI is the prediction of rejection or infarction based on changes in enhancement produced by injection of gadopentetate dimeglumine (Figs. 38-25 to 38-27). After injection of 0.1 mmol/kg, Yuh and colleagues obtained numerous gradient echo scans in the same anatomic location over the pancreas. They found that the normal gland in six cases increased enhancement by 98% during the first minute, whereas the rejecting gland increased enhancement at 1 minute by 42% (6 of 6 rejections). They found that there was little or no change in the calculated T2 value. The abnormal scans preceded chemical evidence of rejection (urinary amylase levels) in four cases (4 of 6 rejection cases). They concluded that T2 intensity was a poor indicator for rejection and favored the use of this new enhancement method.

Pancreatic Nonendocrine Tumors

Most tumors in the pancreas are adenocarcinomas, which produce characteristic configuration changes and occasional signal change. The two most significant reports on MRI of tumors are those by Steiner and associates²⁴⁴ and Semelka and colleagues.²²⁴ As with CT, these tumors produce contour alterations that exceed normal measurements

Figure 38-25. Coronal fast multiplanar, spoiled, gradient-recalled echo MR images (TR = 150 msec, TE = 4.2 msec, 60-degree flip angle) obtained in a patient with normal pancreas allograft, as confirmed at percutaneous biopsy. Unenhanced image (A) and image obtained 1 minute after the administration of gadolinium-based contrast material (B) demonstrate avid enhancement through a normal-sized pancreatic allograft. Note the adjacent enteric anastomosis and renal allograft. (From Krebs TL, Daly B, Wong-You-Cheong JJ, et al: Acute pancreatic transplant rejection: Evaluation with dynamic contrast-enhanced MR imaging compared with histologic analysis. *Radiology* 210:437-442, 1999.)

Figure 38-26. Coronal fast multiplanar, spoiled, gradient-recalled echo MR image (TR = 150 msec, TE = 4.2 msec, 60-degree flip angle) obtained 1 minute after the administration of gadolinium-based contrast material in a patient with moderate acute rejection of pancreas allograft, as confirmed at percutaneous biopsy. Image demonstrates diminished enhancement compared with the enhancement in the pancreas in Figure 38-25B. Mild hydronephrosis of the renal transplant is noted. (From Krebs TL, Daly B, Wong-You-Cheong JJ, et al: Acute pancreatic transplant rejection: Evaluation with dynamic contrast-enhanced MR imaging compared with histologic analysis. *Radiology* 210:437-442, 1999.)

Figure 38-27. Coronal fast multiplanar, spoiled, gradient-recalled echo MR image (TR = 150 msec, TE = 4.2 msec, 60-degree flip angle) obtained 1 minute after the administration of gadolinium-based contrast material in a patient with pancreas allograft infarction that was proved at surgical explantation. There is no enhancement in the enlarged pancreatic allograft or in the duodenal cuff. (From Krebs TL, Daly B, Wong-You-Cheong JJ, et al: Acute pancreatic transplant rejection: Evaluation with dynamic contrast-enhanced MR imaging compared with histologic analysis. *Radiology* 210:437-442, 1999.)

Figure 38-28. A, Pancreatic cancer. MR image with 1-second postcontrast FLASH shows good contrast resolution between the tumor (*arrow*) and pancreas. B, On the Gd-DPTA-enhanced FSSE, a beak sign can be appreciated in the interface between the tumor and pancreas, clearly revealing the pancreatic origin. C, Contrast-enhanced 5-mm CT scan shows a mass in the head of the pancreas. (From Semelka RC, Kroeker MA, Shoenut JP, et al: Pancreatic disease: Prospective comparison of CT, ERCP, and 1.5-T MR imaging with dynamic gadolinium enhancement and fat suppression. *Radiology* 181:785-791, 1991.)

Figure 38-29. FSSE (TR = 500 msec, TE = 150 msec) images in a 62-year-old woman with pancreatic cancer. A, The MR images of the body of the pancreas are unremarkable. B, A low-signal-intensity, non-contour-deforming lesion (*arrow*) in the head proved to be cancer at surgery. C, Noncontrast 5-mm CT scan does not demonstrate the non-contour-deforming pancreatic cancer. (From Semelka RC, Kroeker MA, Shoenut JP, et al: Pancreatic disease: Prospective comparison of CT, ERCP, and 1.5-T MR imaging with dynamic gadolinium enhancement and fat suppression. *Radiology* 181:785-791, 1991.)

Figure 38-30. MR image (SE 926/10) shows pancreatic cancer (curved arrow) in the head of the pancreas, producing distal ductal dilatation (arrow).

or apparent discrepancy between various portions of the gland. On unenhanced scans, Steiner and associates²⁴⁴ reported, 61% (20 of 32) of the tumors had an intensity less than that of normal pancreas, whereas 40% (13 of 32) of the tumors had intensities greater than that of the normal gland. In a similar way that the avascular tumor produces a decreased density with intravenous urographic contrast

material on CT, gadolinium-enhanced MR images can show a difference in the intensity of such tumors compared with the normal gland (Figs. 38-28 to 38-30).

Although the point has not been emphasized, it is apparent that if problematic cases of staging for operability arise, MRI would be extremely well suited to evaluate the status of the peripancreatic vascular system. Encroachment of the portal or superior mesenteric vein would be quite easily detected on MRI.

MRI offers a viable alternative to CT if a specific case is problematic or allergy to contrast agents is an issue. No authors have asserted that MRI is the preeminent study for tumor, but all, including my colleagues and I, recognize the potential for the future.

Authors who have reported indicate that MRI offers no significant advantages over CT for evaluating the pancreas for neoplasia. Further progress is needed in refinement of signal-to-noise ratio, spatial resolution, motion suppression, and bowel opacification before MRI might become competitive with CT.

Cystic Tumors

There is only one extensive report in the literature about the usefulness of MRI for the diagnosis and evaluation of cystic tumors of the neoplasm, by Minami and associ-

Figure 38-31. Microscopic adenoma in tail of pancreas. A, T1-weighted MR image (SE, TR = 600 msec, TE = 17 msec) shows a low-intensity mass, the margin of which appears lobulated. B, T2-weighted image (SE, TR = 2000 msec, TE = 75 msec) shows a mass higher in intensity than that of subcutaneous fat, with a lobulated margin. Its contour can be evaluated easily. Septa are seen as thin, dark lines (arrows). C, Contrast-enhanced CT scan shows a low-attenuation mass with a lobulated margin and thin septa (arrowheads). (From Minami M, Itai Y, Ohtomo K, et al: Cystic neoplasms of the pancreas: Comparison of MR imaging with CT. *Radiology* 171:53-56, 1989.)

Figure 38-32. Microcystic adenoma in the body of the pancreas. *A*, T2-weighted MR image (SE, TR = 2000 msec, TE = 75 msec) shows a hyperintense tumor that appears inhomogeneous in intensity owing to the low intensity of a central scar. *B*, Enhanced CT scan shows a lobulated tumor with a calcified central stellate scar. (From Minami M, Itai Y, Ohtomo K, et al: Cystic neoplasms of the pancreas: Comparison of MR imaging with CT. *Radiology* 171:53-56, 1989.)

ates.^{178a} These researchers studied five microcystic adenomas and seven mucinous (macrocytic) neoplasms (study was not prospective or blinded). Three cystadenomas and four cystadenocarcinomas were studied with both CT and MRI. The observations and conclusions of the authors were that MRI was equivalent to or slightly better than CT for

these tumors because MRI was better able to demonstrate the cystic content by virtue of the different signal (Fig. 38-31). The cystic material was low intensity on the T1-weighted images and high intensity on the T2-weighted images (Figs. 38-32 and 38-33). Attempts to characterize lesions as either microcystic and mucinous or to distinguish

Figure 38-33. Mucinous cystadenocarcinoma in the tail of the pancreas. *A*, T1-weighted MR image (SE, TR = 400 msec, TE = 35 msec) shows a large, round mass with two compartments. The larger one is higher in intensity and has small high-intensity spots. *B*, T2-weighted image (SE, TR = 1600 msec, TE = 70 msec) shows septa of the tumor as low-intensity lines. The two compartments also have slightly different signal intensities. *C*, Enhanced CT scan shows a large cystic mass with a bizarre septum of irregular thickness and papillary projections. The cystic compartments are almost equal in attenuation. (From Minami M, Itai Y, Ohtomo K, et al: Cystic neoplasms of the pancreas: Comparison of MR imaging with CT. *Radiology* 171:53-56, 1989.)

benign from malignant (cystadenoma from cystadenocarcinoma) were not possible on the basis of MRI appearance alone. Variation in signal between different loculations is more common with mucinous tumors, but it can also occur with serous tumors.

The authors' conclusion was optimistic but cautious in stating that MRI was equivalent or slightly superior to CT by virtue of sensitivity to difference in intensity of the different cavities and the better definition of the outer contour of the masses. They also noted that further improvement would be important if better spatial resolution and differentiation between serous and mucinous material were to be achieved.

Endocrine Tumors

A variety of endocrine tumors have been studied with MRI and reported in the literature. Although my colleagues and I have not accumulated a large number of such cases, we have observed the same advantages reported by others for MRI in evaluating these cases.

The signal intensity of endocrine tumors of the pancreas is much different from that for nonendocrine tumors. Such tumors show configuration changes as one might expect, but also, the intensity of the tumor is higher on T2-

weighted images than that of the normal pancreas or the typical pancreatic adenocarcinoma (Figs. 38–34 and 38–35).

With the evolution and development of MRI, its usefulness for the detection of endocrine tumors is proven without question. Early reports using slow pulsing sequences showed disappointing results for detection of these lesions by imaging, with the greatest diagnostic success achieved by angiography. Because these tumors are very rare and the literature is rather sparse, I have included the older data as well as the new data so that the reader will have appropriate perspective when considering the topic.

One of the larger studies, reported by Frucht and colleagues,⁷¹ evaluated the prospective usefulness of various imaging modalities, including CT, ultrasonography, MRI, and angiography, for the detection of gastrinoma (outside of the liver). The results are rather surprising considering the theoretical advantage of MRI and CT. The authors used spin-echo (SE) imaging with T1 and T2 weighting as well as some short T1 inversion recovery imaging. Of the 22 cases of extrahepatic gastrinoma, 17 were within the pancreas and 3 were outside. MRI was successful in detecting lesions in only 4 of the group, and CT was successful in detecting the lesion in only 9 of the group (Fig. 38–36). The most effective imaging system used was angiography, which detected 16 lesions. The addition of MRI or CT did

Figure 38–34. A, Transverse T1-weighted SE image (TR = 550 msec, TE = 11 msec, two signals acquired) without fat suppression shows the insulinoma (arrow) as a mass of lower signal intensity than that of the normal pancreatic parenchyma (p). B, Transverse T1-weighted SE image (TR = 550 msec, TE = 11 msec, two signals acquired) with fat suppression shows the insulinoma also as a low-signal-intensity lesion (arrow). In this case, however, the signal intensity difference between the lesion and the adjacent parenchyma (p) is smaller; therefore, the lesion is less conspicuous. C, Transverse T2-weighted SE image (TR = 2500 msec, TE = 80 msec, two signals acquired) without fat suppression demonstrates the insulinoma as a mass of higher signal intensity (arrow) than that of the normal pancreatic parenchyma (p). (From Thoeni RF, Ullrich G, Mueller-Lisse J, et al: Detection of small, functional islet cell tumors in the pancreas: Selection of MR imaging sequences for optimal sensitivity. *Radiology* 214:483–490, 2000.)

Figure 38-35. A, Transverse T1-weighted SE image (TR = 550 msec, TE = 14 msec, one signal acquired, with fat suppression) shows a 1.5-cm lesion (arrow) near the tail of the pancreas (p). CT also depicted the lesion in this patient with an insulinoma. B, Transverse breath-hold T1-weighted fast multiplanar spoiled gradient-recalled echo (GRE) image (TR = 120 msec, TE = 4.2 msec, one signal acquired, 70-degree flip angle) also demonstrates the insulinoma (arrow), but less conspicuously. p, = pancreas. C, Transverse T2-weighted fast SE image (TR = 4000 msec, TE = 102 msec/effective, three signals acquired) without fat suppression shows the lesion (arrow) as a mass of low signal intensity. p, pancreas. D, Transverse breath-hold fast multiplanar spoiled GRE image (TR = 120 msec, TE = 4.2 msec, one signal acquired) with gadopentetate dimeglumine enhancement shows the mass (arrow) as an enhancing lesion of higher signal intensity than that of the normally enhancing parenchyma (p). (From Thoeni RF, Ullrich G, Mueller-Lisse J, et al: Detection of small, functional islet cell tumors in the pancreas: Selection of MR imaging sequences for optimal sensitivity. *Radiology* 214:483-490, 2000.)

not improve the results because no other lesions were found by the techniques. Tham and others²⁵⁰⁻²⁵² made similar observations, noting that MRI was superior to CT for detecting endocrine tumors (Fig. 38-37), but angiography was still superior to both.

With the advent of faster pulsing sequences and refinement of the contrast agent administration, the current success rate of MRI for detection is excellent. In its current state, proper MRI scanning can diagnose 85% of islet cell tumors 2 cm or smaller. The most significant article on this topic was by Thoeni and associates,²⁵⁴ who studied 28 consecutive patients. In this group, they successfully diagnosed 17 of 20 patients with tumors and had 8 true-negative evaluations. The specificity was 100%; positive

predictive value was 100%, and negative predictive value was 73%. The most successful pulsing sequences were the T1-weighted SE images with fat suppression and nonenhanced gradient recalled echo (GRE) images, which showed 75% of lesions (see Figs. 38-34 and 38-35). T2-weighted conventional SE with fat suppression diagnosed 65%. Other useful sequences were gadolinium-enhanced, spoiled GRE in 12 (60%), and T2-weighted fast SE in 7 of 10 patients (70%). This later work is extremely important, because before MRI had been developed, there was no simple means of preoperative diagnosis of these tumors. Endoscopic ultrasonography was capable of detecting such lesions, but the technique is quite expensive and rather invasive. Intraoperative ultrasonography is virtually 100%

Figure 38-36. A, Selective arteriogram of a small dorsal pancreatic branch shows a 3-cm hypervascular mass (arrows) in the body of the pancreas just to the left of the spine. B, CT scan shows the mass protruding from the anterior surface of the pancreas (arrowheads). C, T1-weighted MR image shows the mass with an area of slightly decreased signal intensity compared with the pancreas (arrowheads), but the mass is difficult to distinguish from the surrounding structures. D, On the T2-weighted image, the gastrinoma reveals increased signal intensity (arrowheads). E, The tumor is far more apparent on the sequence with short inversion-recovery image (STIR) (arrowheads) as a focus of very high signal intensity. (From Frucht H, Doppman JL, Norton JA, et al: Gastrinomas: Comparison of MR imaging with CT, angiography, and US. *Radiology* 171:713-717, 1989.)

accurate, but an accurate noninvasive test such as MRI permits better procedure planning and can avoid laparotomy in selected cases.

CT Imaging of Pancreatic Disease

Pancreatic Duct

The best technique to visualize the pancreatic duct in both normal and abnormal situations requires the adminis-

tration of urographic contrast material and selection of optimal scanning parameters.^{62, 95}

For best visualization, maximal enhancement of the parenchyma relative to the duct should be produced by a sustained intravenous injection of urographic contrast material by mechanical injector with simultaneous or immediately subsequent CT scanning of the pancreas. The recommendations of exact injection rates may vary from one institution to the next, but the dosage and rate suggested in the previous section on technique are adequate.

Occasionally, the normal duct can be visualized with 8-

Figure 38-37. A 55-year-old woman with multiple endocrine neoplasia type I and Zollinger-Ellison syndrome for 18 years exhibits a tumor of the body of the pancreas with lymph node and bone metastases. A, CT scan after intravenous contrast administration demonstrates enlargement of the body of the pancreas (P) and lymph node metastases (N) that are isodense. B, T1-weighted (SE, TR = 300 msec, TE = 20 msec) MR image shows the pancreatic tumor (P) and the lymph node metastases (N) with a homogeneous low signal intensity compared with that of the normal liver parenchyma. The sharply delineated contours of the multiple lesions are readily visible. C, T2-weighted (SE, TR = 2000 msec, TE = 50 msec) MR image reveals the slightly inhomogeneous high signal intensity of the pancreatic tumor (P) and lymph node metastases (N). (From Tham RTOTA, Falke THM, Jansen JBM, Lamers CBHW: CT and MR imaging of advanced Zollinger-Ellison syndrome. J Comput Assist Tomogr 13:821-828, 1989.)

mm-thick scan slices. More consistent visualization of the duct can also be achieved by setting the scanning parameters to optimize contrast and spatial resolution. The best approach is to optimize the spatial resolution in the XY as well as the longitudinal plane. Resolution in the XY plane is improved by using a small field of view to maximize the number of pixels within the anatomy being imaged and

using thin scan slices of 2 to 4 mm. These thin sections are necessary to minimize the partial volume effect in the longitudinal plane, considering that the diameter of the normal duct is 2 to 6 mm. The advantage of the thick slices is that the entire duct can be seen through the length of the gland, and most cases of pathologic dilatation can be routinely imaged without the optimized scanning parameters. Thin slices are advantageous in that the anatomy is better defined, but in most cases, the segments of the duct appear on different scans. With multislice scanners, the normal pancreatic duct is visible on virtually all scans because the routine slice thickness is always 3 mm or less (see Figs. 38-2 and 38-14).

Pancreatitis Effects on Duct

Acute pancreatitis may produce dilatation of the duct, especially if there is superimposition of acute inflammation on a baseline of chronic changes (Fig. 38-38) or, rarely, an acute obstruction of the duct by a calculus (Fig. 38-39) or pseudocyst (Fig. 38-40).

Chronic inflammation produces fibrosis, which, depending on its anatomic location and extent, may result in diffuse dilatation, diffuse stenosis, or segmental narrowing of the duct; the CT scan or MR image directly reflects these gross anatomic findings. In patients who have diffuse narrowing of the ductal system that is significantly attenuated, the CT scan is unlikely to show any positive findings.

When fibrosis occurs close to the head of the gland and is producing partial obstruction, moderate dilatation of the duct, which appears as a fluid-density tubular structure within the gland, occurs. When fibrosis occurs intermittently along the length of the duct, a string of ectatic areas is produced, resulting in the appearance of sacculations on the duct on the CT scan. On occasion, one portion of the duct is more isolated than the others, and a buildup of fluid in a localized area, which appears as a cystic mass on the scan, is produced. This cyst mass, which cannot be distinguished from a pseudocyst by imaging alone, is called a *retention cyst* (Figs. 38-40 and 38-41). It differs from a pseudocyst in that the wall is lined by epithelium of the duct; if the epithelium remains in place for a sufficient time, the ductal lining may atrophy, so ductal elements may not be detectable on pathologic examination. Differentiation of retention cysts from pseudocysts may be difficult because pseudocysts may coexist with or cause ductal dilatation. The nature of a cystic abnormality can be best differentiated by ERCP. Dilatation of the secondary ductules produces clusters of cysts (see Fig. 38-41), which are typically fluid density but may calcify if chronic disease persists.

Ductal Calcification

The calcium deposits that can occur in the parenchyma of the gland can also occur in the wall or the lumen of the duct (Figs. 38-42 and 38-43). The cause and pathophysiology of this process are not well understood. The presence of such deposits, however, should be detected at the earliest time so that corrective measures, such as surgical ductal

Figure 38-38. A, Pancreatic duct dilatation may occur in association with acute pancreatitis superimposed on chronic pancreatitis. This unenhanced scan shows inflammatory fluid adjacent to the distal tail and hilum of spleen (*curved arrow*). Without intravenous contrast material, visualization of parenchymal or ductal changes is difficult. B, After intravenous administration of contrast material, ductal dilatation (*vertical arrow*), is seen as well as subtle decreased density in the head (*curved arrow*).

Figure 38-39. A, Longitudinal reconstruction from multislice scans of pancreas shows stone in pancreatic duct, designated by the large, open arrow. B, Reconstruction endoscopic view of the pancreatic duct shows calculus in the head of the pancreas (*arrow*), at the end of the view of the duct.

Figure 38-40. A, Pancreatogram shows diffuse dilatation with a central ectasi (*arrow*). B, CT scan shows central dilatation of the main pancreatic duct, resulting in a small retention cyst (*arrowhead*).

Figure 38-41. CT scan shows mild dilatation of the central portion of the duct with saccular dilatation distally (arrow), resulting in a retention cyst.

drainages, can be contemplated if clinically indicated. The spectrum of symptoms associated with a calculus in the duct is quite wide. Some patients are asymptomatic, some experience atrophy of the gland (Fig. 38-44), and some may even have life-threatening inflammation after ductal enterostomy.

Ductal Gas

Air can appear in the duct, which may be a result of a fistula or other more benign conditions. Air can also occur after ERCP (Fig. 38-45A), as a result of papillotomy (Fig. 38-45B), from surgery (Fig. 38-45C), or in some patients

Figure 38-42. CT scan shows dilatation of pancreatic duct with calcifications in the wall (arrow).

Figure 38-43. Chronic inflammation has produced intense calcification in the pancreatic duct, atrophy of the gland, and calcifications of the secondary ductules of the gland.

simply as a result of a patulous sphincter of Oddi (Fig. 38-45D). One could certainly hypothesize that cholangitis or another infectious process could spread gas to the duct, but I have not observed this nor seen it reported.

Ductal Changes from Neoplasm

Several authors have reported on ductal changes seen in neoplasm, including Berland and colleagues,²² Freeny and others,⁶⁴⁻⁶⁷ and Muranaka and associates.¹⁸² There is a consensus among authors that high-quality modern CT and MRI reliably demonstrate the appearance and status of the duct. Recognizing the changes produced by inflammation as noted previously, these authors point out that uniform, severe dilatation of the duct can be produced by either inflammation or neoplasm (Fig. 38-46). The frequency and reliability of MRI and CT in differentiating inflammation from neoplasm have been variable among these studies.

Karasawa and coworkers¹²⁷ reported their experience with CT pancreatogram in patients with pancreatitis and carcinoma. They stated that ductal dilatation caused by these entities could be distinguished in a large number of cases. They reported that smooth or beaded dilatation was commonly associated with carcinoma; dilatation occurred in 56% of patients with neoplasm. Ductal dilatation occurred in 58% of patients with pancreatitis, and irregular dilatation was seen in 73% of these patients. The researchers found that patients with carcinoma tended to have a larger duct, average 8.7 mm compared with 6.7 mm in patients with pancreatitis. They also noted that the ratio of the duct to the overall dimension of the gland was greater with carcinoma because of atrophy of the acinar elements associated with complete obstruction; if the ratio of duct to gland was greater than 0.5, carcinoma was likely.

Freeny and others⁶⁴⁻⁶⁷ reported that 108 of 159 patients (68%) had ductal dilatation. In 90 of 108 patients, the margins of the duct were smooth and parallel. In 18 of 108, they appeared beaded or irregular. Pancreatic parenchyma was atrophic in 82% of the patients with ductal dilatation.

Figure 38-44. A, A calculus in the ampulla (arrow). B, Obstruction of the pancreatic duct (arrows) resulting from calculus. The pancreas has autolyzed so only the fat remains within the parenchymal area. (From Patel S, Bellon EM, Haaga J, et al: Fat replacement of the exocrine pancreas. AJR 135:843-845; copyright by American Roentgen Ray Society, 1980.)

Figure 38-45. A, Small bubbles of gas (arrow) can be introduced into the ductal system by pancreatograms. B, Postsphincterotomy at ERCP. After interventional procedures on the common or pancreatic duct, small air collections can be seen within the head of the gland (arrow). C, Patient with calcifications has air (arrow) in the duct containing calculi. Air has refluxed from the bowel through an anastomosis through the duct from a Puestow procedure. D, Air (arrow) has refluxed into the common duct because of an incompetent sphincter of Oddi.

Figure 38-46. Sequential changes in the pancreatic body on CT in patients with pancreatic head carcinoma. This patient was followed clinically because of poor respiratory function. Carcinoma was confirmed by postmortem examination. *A*, Initial CT scan shows marked enlargement of the pancreatic body. *B*, Two months later, the width of the pancreatic body is decreased, and a smooth, narrow pancreatic duct is seen continuously. *C*, Four months later, the pancreatic body has become normal in size. *D*, Atrophy of the pancreatic body and marked dilatation of the pancreatic duct with a beaded contour are demonstrated 7 months later. (From Muranaka T: Morphologic changes in the body of the pancreas secondary to a mass in the pancreatic head: Analysis by CT. *Acta Radiol* 31:483-488, 1990.)

Differentiating Disease According to Ductal Changes

The information provided by the studies cited in the preceding section is helpful for an overall perspective of pancreatic duct assessment, but the most definitive work to date on this topic was by Muranaka and coworkers.¹⁸² These researchers noted that differentiation of benign from malignant disease in the specific case is still not always possible. The configuration and size of the duct depend on the degree and duration of obstruction. Muranaka and coworkers¹⁸² reported that pancreatic duct dilatation is relatively uncommon in small tumors but dilatation of the duct and atrophy of the gland progress with tumor growth. The increased ratio of duct to gland occurs with late tumor progression. Neoplasms and inflammatory processes can produce partial or complete and slow or quick obstruction of the duct. The guidelines proposed by earlier authors are beneficial; that is, if the ratio of the diameter of the duct to the overall diameter of the parenchyma is 0.5 or greater, the chance of a neoplastic origin is more likely (Fig.

38-47). The detailed analysis of these findings provided by Muranaka and coworkers¹⁸² is illuminating as a reference source (Table 38-1).

Pancreatitis

Inflammation of the pancreas is produced by the release of proteolytic, lipolytic, and other enzymes; the acute process produces a serious clinical state that has numerous life-threatening complications. Chronic pancreatitis is associated with recurrent acute bouts and produces significant long-term morbidity.⁵

Causes of pancreatitis are numerous and include gallbladder disease, trauma,¹⁶² alcohol ingestion, drug use, hypercalcemia, hyperlipidemia, vascular disease, infection, uremia, diabetic coma, heredity, and unknown causes. Regardless of the initiating cause, once there has been activation of the various enzymes, severe inflammation ensues. The spectrum of acute pancreatitis is broad, and it may

Figure 38-47. A, CT scan of a patient with chronic pain, which shows severe dilatation of the pancreatic duct. The diameter of the duct is more than 0.5 the diameter of the gland (arrow). The duct is somewhat tortuous, which some authors suggest may be consistent with pancreatitis. B, A lower section on CT scan shows a small high-density mass (arrow) within the fat density gland, which proved to be cancer at surgery.

produce a benign, self-limited episode or worsen into a self-perpetuating fulminant course.

The symptoms of pancreatitis include abdominal pain, nausea, and vomiting. Classic laboratory findings include elevated levels of serum amylase and lipase and depressed levels of serum calcium. Occasionally there are also elevations of serum glucose and triglycerides.

Although the diagnosis of either acute or chronic pancreatitis is usually made clinically, imaging procedures at times may provide valuable information about the cause, course, progression, prognosis, and complications of the disease.^{4, 264} The following sections discuss the different forms of pancreatitis and are intended to make the radiologist an integral part of the clinical team that cares for such patients.

Causative Factors

The most valuable contribution that can be made by CT examination is the detection of the primary cause of the inflammatory process so that remedial steps can be taken. The most important finding on a study of a patient with pancreatitis is the presence of biliary or gallbladder calculi. Calculi can be the cause of severe pancreatitis, and they are one of the few problems that can be easily remedied. The specific appearance of calculi is discussed in Chapter 37, but one should bear in mind that CT is not the modality of choice for biliary or gallbladder calculi. A CT scan may be normal in the presence of gallstones simply because there is minimal density between the stones and the sur-

rounding bile. Ultrasonography is the study of choice and should be performed in all patients with pancreatitis.

In cases of trauma, direct damage can be seen as well as significant trauma in the adjacent structures. In children with pancreatitis, the presence of calcification usually indicates familial pancreatitis. In most instances, the cause of pancreatitis is unknown, let alone detectable on CT or other imaging techniques. The sensitivity of CT for detecting pancreatitis is exceptional, considering that even clinically asymptomatic pancreatitis caused by ERCP can be detected by CT, as noted by Thoeni and associates.²⁵³

Acute Edematous Pancreatitis

Acute pancreatitis is well suited for examination by CT because CT scanning is not impaired by gas as is ultrasonography. If there is an associated ileus or sentinel loop, it will not impede CT examination but may preclude an examination by ultrasonography. The diagnostic signs of pancreatitis include pancreatic and peripancreatic edema, contour changes, duct dilatation (see prior section on the pancreatic duct), and alteration of pancreatic density.

The contour of the gland may change significantly depending on the enlargement of the gland and the amount of fluid and edema (Figs. 38-48 to 38-51). The anterior and posterior margins of the gland may be difficult to delineate because of the presence of edema or fluid in the immediate area of the gland. A slight amount of edema posteriorly makes the fat plane between the gland and vessels slightly denser, whereas a large amount of high-

Figure 38-48. Early edematous pancreatitis shows enlargement of the gland diffusely and subtle amounts of edema fluid along the margins of the gland (*arrow*).

density fluid may totally obscure the margins of the splenic vessels. The pancreas may increase or decrease in size, depending on the stage of inflammation (Figs. 38-52 and 38-53). Edema fluid may extend along the anterior ligamentous pathways, such as the mesentery, hepatoduodenal ligament, or the mesocolon (Fig. 38-54). With the mesocolon originating from the anterior surface of the pancreas, spread of the inflammation resulting in a sentinel loop is quite common in the hepatic, transverse, or splenic flexure portion of the colon.

Figure 38-49. With large accumulations of fluid, the fat plane between the gland and the splenic vein becomes higher in density (*arrow*). Note also the subtle edema spread throughout the mid-portion of the mesentery.

Figure 38-50. CT scan shows subtle fluid around the body of the gland but early accumulation of fluid in the lesser sac (*arrow*) behind the antrum of the stomach and in front of the pancreas. Also note the small gallstones in the gallbladder (*curved arrow*).

Density alterations within the gland result from either fluid accumulation (see Figs. 38-52 and 38-53) or necrosis. Edematous pancreatitis can be differentiated from necrotizing pancreatitis by the injection of contrast material (see Fig. 38-51) because the normal gland enhances but the avascular necrosis does not. Maier¹⁶¹ found in operatively confirmed cases that edematous pancreatitis maintains uniform enhancement without alterations of density; necrotic devascularized areas do not enhance. In subtle cases, there may be no positive laboratory findings; the serum amylase and lipase levels may be normal.

Further progression of the inflammation most commonly produces ascites, which can fill the adjacent peritoneal

Figure 38-51. Severe pancreatitis produces large amounts of pancreatic and peripancreatic edema. The fat plane (*arrow*) between the splenic vein and the gland is dense. Also note the early necrosis (N) in the head, which shows decreased enhancement compared with adjacent normal parenchyma.

Figure 38-52. A, CT scan shows focal enlargement of the tail (arrowhead) secondary to pancreatitis. B, After resolution, the gland returned to normal size (arrowhead), but residual focus of fibrosis remains.

space, including the greater peritoneal cavity and lesser sac. Involvement of the general cavity produces ascitic fluid in the adjacent dependent spaces, such as the paracolic gutters and Morrison's pouch. The lesser sac, being immediately anterior to the gland, is the space most commonly involved by accumulation of fluid (see Fig. 38-50). Fluid collections or subsequent pseudocysts can occur in either the inferior or the superior medial recesses of the lesser sac (Fig. 38-55).

The anatomic area second in frequency of involvement by continued inflammation is the anterior perirenal fascia on either the right or left side depending on whether the head or the body of the gland is involved. The fluid may extend either cephalad to involve the bare area behind the liver or spleen or caudad to involve the retroperitoneum down into the pelvis by the psoas muscle. The amount of the fluid can be so great that it produces distention of the fascia, creating a mass (see Fig. 38-56). With the sparing of the perinephric fat, this appearance has been given the name "halo sign" by Susman and colleagues.²⁴⁶

Progressive inflammation and spread of edema can produce pronounced extension into contiguous organs or bowel.¹⁷⁸ Inflammatory involvement of the mesentery and mesocolon may produce sufficient edema to cause lym-

phatic and venous congestion, leading to an ileus or sentinel loop of the adjacent bowel. Involvement of the stomach and edema can produce such severe thickening that they may simulate a mass. Digestion of the enzymatic material along the vasculature of the ligaments or through fascia can result in direct involvement of the liver, spleen, or even the kidney with ultimate formation of pseudocysts in those organs.

One specific area of inflammatory spread that has been the source of some controversy is the perivascular fat plane around the superior mesenteric artery. Traditional teaching has held that only tumors can produce this appearance of encasement, but Schulte and colleagues²²³ and other researchers have documented the occurrence of loss of the fat plane with pancreatitis in addition to neoplastic inflammation. This finding can be seen in both acute and chronic pancreatitis.

Chronic Pancreatitis Mimicking Adenocarcinoma

Numerous authors, including Johnson and Outwater,¹²¹ Kim and associates,¹³¹ and Kusano and coworkers,¹⁴² have

Figure 38-53. A, CT scan shows an area of decreased density (arrow) within the gland that represents focal pancreatitis. B, ERCP shows enlargement of the duct (arrow) in the central part of the gland; enlargement is typical of pancreatitis.

Figure 38-54. Large amount of edema spreads throughout the mesentery and into the perirenal fascia. Note the wall thickening of the descending colon. It is my belief that secondary infection of fluid collections occurs when bacteria are cleared through the lymphatics but become lodged in fluid collections and propagate.

reported that chronic pancreatitis can look virtually identical to pancreatic adenocarcinoma on CT and MRI studies. Johnson and Outwater¹²¹ studied a group of 28 patients with adenocarcinomas and 7 patients with chronic pancreatitis, using the best available MRI sequences at the time and gadolinium injection. Normal glands enhanced in a predictable fashion, but both tumor and fibrotic areas of pancreatitis showed delayed enhancement patterns that

Figure 38-55. With sustained inflammation, ascitic fluid accumulates in spaces such as the superior recess of the lesser sac, which borders the caudate lobe C of the liver (straight arrow). Also note thickening of the splenic flexure of the colon (curved arrow).

were indistinguishable (see Figs. 38-20 and 38-21). Kim and associates¹³¹ studied 7 patients with focally enlarged masses in the pancreas, using the current MRI and CT techniques with the appropriate contrast enhancement. In all patients pathologic analysis confirmed local fibrosis in the masses. The imaging appearance of all of the masses mimicked that of focal adenocarcinoma, with no specific differentiating findings.

Evolution of Inflammation

Pancreatic inflammation has many different appearances as it evolves through various stages. In the earliest phases, it appears as a subtle increase in the density of the fat. As fluid accumulates, it may fill tissue spaces until it develops well-defined margins. Although no formal study correlating the appearance with fluid composition has been made, it has been my perception that if the process becomes more severe, the density of the fluid increases. If the inflammatory fluid remains low in density or changes from high density to low density, it seems that resolution soon follows. The resolution of the edema and fluid collections may be complete, but some may remain as residual collections of enzymatic material, thereby creating pseudocysts (see Fig. 38-67).

Although observations about the extent and nature of fluid distribution are important, the most significant diagnostic signs that should be sought are those related to necrosis and possible infection. Both of these problems can have a devastating effect on a patient if they are not treated promptly and correctly. A number of surgeons and clinicians, including Maier,¹⁶¹ have stressed that both necrosis and infection are accurate predictors of the ultimate outcome of severe pancreatitis and also have used them as indications for surgical intervention, as noted in the later section on necrotizing pancreatitis.

Figure 38-56. CT scan showing extensive fluid collections extending caudally into retroperitoneal fascia (arrows). The right side is more severe than the left side. Distention of fascia around normal peripheral fat has been called a "halo sign" by Susman and associates.²⁴⁶

Differentiating Inflammatory Mass from Neoplasm. Thickening of the perirenal fascia, a nonspecific sign, can be associated with any entity that produces edema or obstructs the flow of lymphatics (e.g., masses, infection). As a practical matter, however, thickening of the perirenal fascia is more common with inflammation in both acute and chronic pancreatitis.^{187a} Published data have shown that thickening of the left perirenal fascia occurs infrequently in early pancreatic carcinoma. This is not an absolutely reliable finding, because in occasional cases, pancreatic cancer can coexist with inflammation. Another finding commonly mistaken as pathognomonic of neoplasm is loss of the perivascular fat plane, which can occur with inflammation as well as neoplasm.^{143, 148, 183}

Differentiating Tissue Edema from Fluid Collection. When inflammation is severe, a large amount of edema occurs as well as the accumulation of fluid. Differentiation of these two entities can be made by looking for the presence of small "fat islands" within the fluid density. These areas represent intact areas of normal tissue and fat uninvolved with edema fluid, thereby distinguishing them from collections of liquefied tissue or fluid that may require drainage.

Spontaneous Hemorrhage with Acute Pancreatitis. A sudden loss of blood sufficient to produce a sudden drop in a patient's hematocrit value, can occur in an inflamed area. Such a sudden blood loss in the area of the pancreatic bed is easily detectable on CT as an increased-density collection of material in the inflamed area. This blood loss can result from a diffuse leakage of inflamed granulation tissue or a break in a vessel damaged by digestive enzymes. Hemorrhage associated with pancreatitis should not be confused with *hemorrhagic pancreatitis*, a term that has been used in the past to refer to severe or life-threatening pancreatitis.

From experience with CT procedures and surgical procedures, it is clear that virtually all fluid or inflammatory material obtained from an acute inflammatory process appears bloody regardless of the severity of the disease. The irrelevance of the hemorrhagic nature of inflammatory fluid was noted by both Isikoff and colleagues¹⁰⁹ and Lawson and others.¹⁴⁴⁻¹⁴⁶ They reported detecting high-density material believed to be blood in the inflammation associated with pancreatitis. Both groups noted that the finding was not consistently related to the severity of the disease, and Lawson stated, "There did not appear to be any correlation between the mortality, severity of the illness, or extent of retroperitoneal necrosis and the presence or absence of hemorrhage as observed at surgery."

Severe Necrosing Pancreatitis. Severe pancreatitis, regardless of the descriptive terms or the method of categorization, is a devastating disease with a reported mortality rate between 33% and 100%.^{122, 161, 262} Before CT scanning, the objective assessment of the anatomic extent of pancreatic inflammation and determination of the degree of involvement were difficult to achieve.¹⁹¹

Clinically, this entity has been virtually impossible to distinguish from severe edematous pancreatitis. Previously the most reliable method of assessing the severity of the

disease was careful examination and correlation of clinical signs and relevant serum laboratory values, such as serum calcium, serum methemalbumin, and hematocrit. Paracentesis was occasionally performed to obtain fluid for analysis. Data published by surgeons have shown that the standard clinical method for grading severity of disease, such as Ranson's criteria or the APACHE (Acute Physiology and Chronic Health Evaluation) II, are not good indicators for either operative intervention or prognostication.

The most valuable diagnostic method for evaluating the status of the pancreas with severe inflammation is a good-quality CT scan enhanced by adequate doses of intravenous contrast material, as noted in the technique section.^{43, 120, 133, 136} The normal gland shows considerable enhancement as a homogeneous pancreatogram. The devascularized or necrotic gland shows a lack of this enhancement in the focal area of necrosis (Figs. 38-51 and 38-57). Furthermore, authors have shown that the larger the area of devascularized necrosis, the poorer the outcome for the patient, accompanied by a greater probability of secondary infection. The significance of this sign has been studied by several groups, but the importance of this finding was best demonstrated by Block and colleagues.²⁵ These authors compared the effectiveness of CT and ultrasonographic procedures with clinical staging for identifying pancreatic necrosis. They studied 93 patients in a prospective fashion, who subsequently underwent surgical exploration. The group found that CT with enhancement was superior for detection of pancreatic necrosis. Ninety percent of cases of severe necrosis and 79% of cases of minor necrosis were demonstrated with enhanced CT. Ultrasonography was not diagnostic in 24% because of the presence of meteorism. Other observations made by these authors are also noteworthy. They noted that even with CT, there is the risk that the area of necrosis may be larger and that occasionally, an avascular area may be ischemic but not necrotic. Maier¹⁶¹ reported that the contrast-enhanced CT evaluation for pancreatic necrosis was a better indicator for surgery than

Figure 38-57. CT scan performed during contrast enhancement shows large fluid mass in the central portion of the pancreas corresponding to an area of necrosis. Dilated pancreatic duct (horizontal arrow) and fluid extension to stomach (curved arrow) can be seen. Gastric wall is distended with inflammatory fluid on both the anterior and posterior surfaces (arrowheads).

any of the currently accepted clinical methods for grading severity of disease.

Once the diagnosis is made, a diversity of therapeutic regimens is recommended, including conservative management, sump drainage, and pancreatectomy. Serious complications, such as pancreatic abscess, pseudocyst, fistula formation, and endocrine and exocrine deficiency, can result. Despite the fact that diverging opinions on the modes of therapy can be found, all authors agree that expeditious, accurate diagnosis of the problem is needed.^{133, 149} Morbidity and mortality rates for severe pancreatitis are still high.

Distinguishing Infected and Sterile Necrosis. Bittner and colleagues²³ and others^{21, 25, 161} pointed out the importance of differentiating pancreatic abscesses (well-marginated fluid collections) from pancreatic necrosis and infected pancreatic necrosis. The outcome of pancreatitis depends not on the amount or severity of inflammation but rather on the presence or absence of infection. Although abscesses can usually be drained by percutaneous methods, infected necrosis requires surgical evacuation of all infected material and institution of postoperative lavage of the lesser sac. Necrosis tends to become infected, and it is critical that infection be detected.

The inflammatory material with necrotic matter, blood, and enzymes is a good culture medium and has a high susceptibility for secondary infection.⁸ Unfortunately, it is not possible to detect any transition from necrosis to infection on the basis of a CT scan. Serial aspiration samples for culture must be obtained if an infectious process is suspected or if any air is present. In such cases, it is absolutely imperative that the diagnostic aspiration be completely and technically precise, without contamination from intestinal material; passage through bowel negates the reliability of the culture because false-positive findings may result and, more important, contamination with the gastrointestinal contents may introduce an inoculation, which can lead to infection. (It might be hypothesized that one could distinguish between contamination and infection in the culture results on the basis of the mixed colonic flora obtained. This is incorrect because most authors believe the major source of infection is small gastrointestinal fistulas.)

Anatomic Staging and Prediction of Clinical Severity. With the seriousness of pancreatitis and the difficulty in predicting the outcome, several authors have attempted to devise a method for predicting the outcome of pancreatitis. One imaging approach developed by Balthazar and others¹³⁻¹⁵ parallels Ranson's criteria and has been somewhat useful for staging the inflammatory process

in a slightly different fashion from the simple method of looking for necrosis.^{11, 13}

Balthazar and others¹³⁻¹⁵ devised the following grading system on the basis of CT findings: grade A, normal pancreas; grade B, focal or diffuse enlargement of the gland (includes nonhomogeneous attenuation of gland, dilatation of duct, and foci of fluid within the gland, as long as there is no extrapancreatic edema); grade C, peripancreatic edema and intrinsic abnormalities of grade B; grade D, single ill-defined fluid collections or phlegmon; and grade E, two or more fluid collections or the presence of gas. These researchers found that the patient's hospital course correlated well with these findings and the grading system. Abscess occurred in 21.6% of all patients and in 80% of patients with grade E pancreatitis. The researchers also point out the use of CT to pick up associated findings, such as gallstones and peritoneal and pleural fluid. All deaths occurred in grades C, D, or E pancreatitis, with the majority in grade E.

Balthazar and others¹³⁻¹⁵ also noted that the longer the hospital stay, the higher the grade of pancreatitis. Patients with grade A stayed 13 days; grade B, 17 days; grade C, 25 days; grade D, 31 days; and grade E, 52 days. They also found a correlation between CT findings and the clinical prognostic signs previously described by Ranson; the signs are listed in Tables 38-2 and 38-3.

This information provides a mechanism for effectively communicating in a concise fashion the severity of a patient's pancreatic inflammation. This system, however, does not always correctly predict the outcome. Despite these attempts to predict and manage acute situations, the outcomes are remarkably different from expectations. Sometimes, disease with fairly benign-appearing inflammation can have a precipitous course (Fig. 38-58). Conversely, individuals with more anatomically extensive disease can do well.

Prognostic Indicators. The best method of predicting clinical outcome was evaluated by De Sanctis and colleagues,⁵³ who prospectively compared the merits of the contrast-enhanced computed tomographic (CECT) criteria of disease severity and the APACHE II system. In their study, 35 consecutive inpatients were scanned and a consensus interpretation was performed to provide determination of the CECT grade of the severity index. The APACHE II score was calculated within 24 hours of the CECT.

In my opinion, this is the most significant work performed in the evaluation of pancreatitis in the last 25 years. The imaging field and the clinical science have been refined

Table 38-2. Early Prognostic Signs of Acute Pancreatitis* According to Ranson

Admissions or Diagnosis	Initial 48 Hours
Over 55 years of age	Hematocrit falls more than 10%
White blood cell count over $16 \times 10^3/\mu\text{L}$ ($16 \times 10^9/\text{L}$)	Blood urea nitrogen level rises more than 5 mg/dL (1.79 mmol/L)
Blood glucose level over 200 mg/dL (11 mmol/L)	Serum calcium level falls below 8 mg/dL (2 mmol/L)
Serum lactic dehydrogenase level over 350 $\mu\text{mol/L}$	Arterial Po_2 below 60 mm Hg (7.98 kPa)
Serum glutamate oxaloacetate transaminase level over 250 $\mu\text{mol/L}$	Base deficit greater than 4 mEq/L (4 mmol/L)
	Estimated fluid sequestration more than 6000 mL (6 L)

* Each sign counts as 1 for score.

over this period, so there can be no question as to the validity of this study. The results show that the APACHE II score is the best predictor of the need for admission to intensive care or severity of systemic disease. The CECT, because it provides an assessment of anatomic information, is the best predictor of local complications. This is only logical, because it is known that ultimate mortality of severe disease depends directly on fluid collections, which may be infected, or pseudoaneurysms, which have a propensity to bleed. The most effective strategy is to triage the patient to an acute care environment according to an immediately calculated APACHE II score. Imaging assessment can be performed as clinically indicated.

Presence of Infection

Relative to infection, many studies have noted that no imaging method can determine the presence or absence of infection. The only effective way to do so is to perform a diagnostic aspiration for culture, as discussed in Chapter 62. Several short comments are appropriate. CT is extremely well suited to use during aspirations because of its ability to detect fluid collections and guide accuracy of the procedure. During such procedures, several technical points are relevant. It is always prudent to perform an intense bolus injection to demonstrate possible pseudoaneurysms. The trajectory planning of any diagnostic aspiration should be made to avoid intestinal loops, because contamination of the needle could result in a spurious culture result or,

potentially, contamination of any fluid collection. Finally, one should realize that infection is a dynamic event and may occur during different phases of the pancreatic inflammation. Diagnostic aspirations should be repeated whenever there is a consideration of infection; spontaneous development of infection can occur at any time, so a negative prior aspiration result is meaningless.

Once infection has been discovered, proper management is critical, because the outcome of infected pancreatitis depends on effective drainage. In a limited number of cases, percutaneous methods may work if a fluid collection is well confined and contains very thin material. In many cases, patient survival is contingent on effective surgical drainage.^{28, 29, 241}

Emphysematous Pancreatitis

Emphysematous pancreatitis is a diagnostic term originating from plain-film radiography that describes a life-threatening pyogenic infection of the pancreas caused by gas-forming bacteria. When applied to CT imaging, however, the term describes a wide spectrum of disorders, some of which are severe and some of which are benign and self-limited.

Gas-forming pyogenic infection superimposed on pancreatitis can result from a variety of causes, including spontaneous, hematogenously seeded colonization from gastrointestinal fistula or secondarily from surgical procedure (usually cystotomy). The organisms that most commonly produce gas are *Escherichia coli*, *Enterobacter aerogenes*, and *Clostridium*. The most infamous of these bacteria are the *E. coli*, which classically produce emphysematous pancreatitis associated with a high mortality rate in diabetic patients. Because plain-film radiography has a much lower contrast resolution than CT, it is virtually impossible to detect gas in the pancreas in an early phase of development on plain-film radiography. Conversely, the slightest amount of gas can be detected with CT; the presence of gas caused by a multitude of disorders is possible.

With the advent of CT, with its superlative axial anatomic images and contrast resolution, the diagnosis of gas in the pancreas has become much easier from a detection standpoint but more complex because of the multitude of entities that can be seen and must be differentiated.

A number of authors have noted that there may be a discrepancy between the imaging appearance of the gland and the clinical appearance in many cases of emphysematous pancreatitis.¹⁷⁷ A high percentage of cases of emphysematous pancreatitis have resolved without aggressive treat-

Figure 38–58. Patient who died within 24 hours after admission and 8 hours after this study has minimal signs of inflammatory disease around the pancreas (P), even though the cause of death was pancreatitis. Note calculi in gallbladder (arrow).

Figure 38-59. Scan of patient with emphysematous pancreatitis shows fluid collection surrounding the enhancing pancreas (P). Air is distributed in the fluid around the gland as well as in the gland itself (arrows).

ment by drainage (Fig. 38-59). A smaller percentage of cases have a disastrous outcome, regardless of adequate treatment.

In most seriously ill patients with emphysematous changes, there are significant associated problems, such as a gastrointestinal fistula,^{8, 199} which may have developed because of an ulcer,¹⁶⁰ perforation, or another problem. Such patients may do well temporarily, but most eventually experience sepsis and do poorly unless proper expeditious drainage and correction of the basic problem are accomplished. In the case illustrated in Figure 38-59, the patient initially appeared well, and the clinical physicians were not convinced of his serious situation until he suffered cardiorespiratory collapse. While connected to a respirator and supported with vasopressive agents, the patient underwent percutaneous drainage of the pancreas, which effected a cure.

The cause of the gas in patients who do well is in question. Two plausible hypotheses explain these observations. The first explanation is that the gas is a by-product of necrosis. The gas may be nitrogen or another gaseous material, not from gas-forming bacteria but from tissue necrosis. An alternative theory, which I propose, is that the gas is produced by gas-forming organisms or from a small gastrointestinal fistula that closed spontaneously and that may or may not adversely affect the patient, depending on immune status. I have scanned several patients with gas in the pancreas produced by pyogenic organisms who have recovered without surgery or antibiotics. The presence of pyogenic bacteria in both cases was proved by diagnostic aspiration, the specimen for which was obtained by an aseptic method (avoiding bowel) (Fig. 38-60).

The outcome in patients with emphysematous pancreatitis probably depends on their immune status. Some patients who have a competent immune system can handle a borderline colonization or infection from their own flora. Those who are immunocompromised or become debilitated are unable to mobilize or sustain the competence of the immune system to handle the infection. Such patients become severely ill and can even die.

Management. The management and disposition of patients who have emphysematous pancreatitis should be based on clinical, laboratory, and imaging data. First, it is important to ensure clear communication among the internist, surgeon, and radiologist. Close cooperation ensures that all physicians are aware of any change in clinical status or imaging appearance so adjustment in patient care can be made without delay.

There does not appear to be any controversy about the best treatment for symptomatic patients with pancreatic gas. These patients require early surgical or percutaneous drainage of infected areas around the pancreas. The methods for draining such areas are discussed in Chapter 62.

In asymptomatic patients, aspiration should be performed under CT guidance at the earliest time, with careful avoidance of intestinal loops or bowel (assuming that other causes of gas have been excluded) (see next section). Careful avoidance of bowel loops is important if the culture of the sample is to be valid. The sample obtained must be

Figure 38-60. A, Baseline CT scan of a patient with a pseudocyst in whom a colonic fistula developed. This scan shows a pseudocyst (C) with an extension to the splenorenal ligament (S). B, Second scan taken 2 days later with the patient prone shows air (arrow) in the posterior fluid collection and fluid extending around the colon (curved arrow).

free of bowel contents. Second, enteric bacteria must not be introduced into a pancreatic fluid collection; such a contaminant could cause an abscess if the pyogenic bacteria grew.

Management of asymptomatic patients should be based on the results of the culture. If the culture is negative, the patient should be observed and CT examinations should be performed regularly until the gas disappears. Any clinical or CT sign of deterioration should result in a re-evaluation, and surgery should be considered.

If the gas does not resolve within 1 week, a second aspiration should be performed in case a sampling or handling error was on the first sample.

If the culture result is positive, one of several courses of action can be taken. First, if the sample aspirated is culture positive, the proper antibiotic medication should be chosen, and surgical drainage considered. If the patient is a poor surgical candidate, percutaneous procedure may be performed to stabilize him or her. This procedure decreases the "toxic load" and, it is hoped, stabilizes homeostasis (e.g., nutrition, cardiovascular system). If the patient remains stable with antibiotic therapy and the emphysematous appearance on the CT scan resolves, no further intervention is required. If the patient improves generally but the gas remains, further investigation is required to determine the origin of the infection (e.g., penetrating ulcer or gastrointestinal fistula) (see Fig. 38–60).

Other Causes of Gas. One of the most common benign

causes of gas in the pancreas is a duodenal diverticulum. The air collection is usually single, well defined, and located just medial to the second portion of the duodenum or in the lower portion of the uncinate process just cephalad to the third portion of the duodenum (Fig. 38–61). The diverticulum may contain a fluid level or even barium if an oral contrast agent has been given.

A penetrating ulcer has one of two appearances. If the ulcer penetration seals, only a single minute collection of gas in the pancreas just adjacent to the duodenal or stomach wall is usually seen. In some cases, edema of the wall can be seen. If a large penetration has occurred and it is not sealed, a large amount of air may be scattered throughout the omental bursa or into an adjacent structure.

Gastrointestinal fistula also produces air in and adjacent to the pancreas (Figs. 38–62 and 38–63). The gas is ill defined and closely related to the stomach, jejunum, duodenum, or colon. It is difficult to ascertain the origin of the fistula on the CT scan; contrast studies of the bowel and injection of contrast material after drainage are most useful.

Other common causes for benign gas in the pancreas are iatrogenic and are usually the result of a recent or remote surgery or interventional procedure. Puestow procedures (enterostomy to the duct) or papillotomy can produce gas in the duct. Freed and colleagues⁶³ reported that with Puestow procedures, when the anastomosis or Roux-en-Y loop was collapsed and contained fluid and gas, confusion with a peripancreatic abscess was very possible. Patients who have undergone internal drainage procedures on pseu-

Figure 38–61. A, CT scan shows a gas collection in the area of the head of the pancreas, which has some ill-defined densities within. Because the patient was febrile, a drainage catheter was inserted (arrow). B, Fluoroscopic study showing contrast material in duodenum and multiple diverticuli; the catheter remains in diverticulum. C, In CT scan obtained after the drainage catheter was removed, the air cavity has reduced in size and has a better-defined margin. This case of duodenal diverticulitis required no further treatment.

Figure 38-62. CT scan shows a large air collection with a contrast level in the cavity behind the head of the pancreas, anterior to the vena cava. Small amounts of air (arrow) are noted in the vena cava due to ulcer in diverticulum (D), which penetrated posteriorly.

docysts (e.g., cystogastrostomies) can have variable amounts of gas and fluid in the cavity (see Fig. 38-61A). Immunocompromised patients experience a long delay in the healing of such cavities (Fig. 38-64). Occasionally, some asymptomatic elderly patients have a patulous sphincter, and spontaneous reflux of air into the ductal system occurs. Rarely gas can appear in vessels when a penetration occurs into adjacent vessels. Spurious findings related to partial-volume effects may be seen (Fig. 38-65).

Pancreatic Abscess

Pancreatic abscesses are a severe, life-threatening problem if not correctly treated. As has been noted previously,

Figure 38-63. CT scan of peripancreatic region shows a small collection of gas in the superior mesenteric vein (arrow). This was secondary to a perforated diverticulum in the small bowel that had tracked into the vein.

the outcome of pancreatic inflammation occasionally depends on the presence or absence of infection. Pyogenic infection of the pancreas can be caused by a variety of organisms introduced by different mechanisms.

Virtually any organism can infect the pancreas,⁵⁴ but most are bacteria or fungi from the gastrointestinal tract. They include many gram-negative and gram-positive organisms and *Candida albicans*. Hurley and Vargish¹⁰⁶ showed significant differences among infections caused by different organisms. In their series, gram-negative infections were polymicrobial and had a high mortality, whereas gram-positive infections were monomicrobial and had a low mortality. (In immunocompetent patients, primary infection from *Candida* probably does not occur; it is probably opportunistic initially after treatment with broad-spectrum antibiotics.) If the causative organism is not gas forming, the appearance of fluid on the CT study is indistinguishable from the appearance in a typical case of suppurative or hemorrhagic pancreatitis.⁵⁸ If there is any question of possible infection in a patient, a percutaneous diagnostic aspiration should be performed.

The mechanisms for introduction of the infection are the same as for emphysematous pancreatitis; they include hematogenous seeding, lymphatic spread, gastrointestinal perforation or fistula,⁹⁹ and iatrogenic responses to some type of procedure. Hematogenous seeding is most likely to occur superimposed on a gland that has some type of baseline problem, such as pancreatic necrosis. It is our impression that patients who have large amounts of fluid around the colon are at risk for infection because of possible lymphatic or venous seeding from enteric flora.

Iatrogenic causes of abscess can also occur after surgical drainage procedures, ERCP,⁵⁴ or percutaneous instrumentation. After an internal drainage procedure during which a stoma between a cyst and a loop of bowel has been created, the pseudocysts become colonized by enteric flora. In most instances, this colonization does not create a problem, but if there is an anatomic region that does not freely communicate with the bowel, a local accumulation of material can result in an abscess. Considering the number of bacteria involved, it is actually surprising that more infections do not occur after such procedures (see Fig. 38-64).

Immune Status

As with any other infection the immune status of the patients with pancreatitis is critical. Those who are immunocompromised may have delayed clinical responses to treatment as well as delayed resolutions of anatomic findings. In such cases, the resolution of the fluid or air collection may take longer than it would in a patient with a normal immune status.

Abscesses Caused by Other Pathogens

In addition to the typical bacteria, abscesses may be caused by fungi, tuberculosis,^{40, 237} parasites, and other pathogens.¹⁴⁸ In such cases, especially if percutaneous culture specimens are to be obtained, proper handling of the material for culture must be ensured. Experience shows

Figure 38-64. A, In immunocompromised patients, resolution of the pseudocyst cavity takes a long time, even after surgical internal drainage. The cavity contains a large amount of fluid and air (arrow) that could be mistaken for an abscess; sinogram showed enteric anastomosis as intact. B, Study performed after removal of the internal drain shows a small residual cavity (arrow) containing minimal air and fluid.

that the appearance of abscesses is nonspecific except for those due to *Echinococcus* (Fig. 38-66). All abscesses appear as fluid collections with variable density depending on the amount of blood and debris. With echinococcal disease, however, daughter cysts should be visible.^{6, 269} Also, in patients with acquired immunodeficiency syndrome (AIDS), one can expect a variety of unusual opportunistic pathogens. Lederman¹⁴⁷ had a patient with toxoplasmosis microabscesses of the pancreas. Noncaseating granulomatous disease such as sarcoidosis of the pancreas has also been reported by Sagalow and associates.²¹⁷

Pseudocysts

A *pseudocyst* is a fluid collection consisting of necrotic material, proteinaceous debris, and enzymatic material that

is confined by a fibrous capsule. The term *pseudocyst* notes the difference between it and other fluid collections within the pancreas that are true cysts (with an endothelial lining) or retention cysts (with a ductal cell lining).²¹⁹

The exact pathogenesis of pseudocysts is not well understood, especially the initiating process, although it is well known that a pseudocyst can result from any significant inflammatory process—either acute or chronic inflammation or acute injury such as trauma. Some authors believe that the fluid in such pseudocysts results from tissue damage, whereas others believe it results from the rupture of ductal elements, which contribute significant amounts of pancreatic secretions. Obviously, both processes must occur, and the cause has no effect on detection, therapy, or prognosis.

Pseudocysts are unique entities because of their protean

Figure 38-65. A, CT scan illustrates an unusual caveat. In this patient, an air density is visible behind the superior mesenteric artery (arrows), which is simply due to an incidental herniation of a portion of a loop of small bowel, below the artery. This finding was of no clinical significance. B, A partial volume averaging of a loop of jejunum adjacent to an area of edema gives a spurious impression of emphysematous pancreatitis. Gas bubbles (small arrows) are trapped in the valvulae conniventes of the duodenum. Note the edema in the retroperitoneal fascia (curved arrow).

Figure 38-66. Unusual infections of the pancreas can occur. This CT scan shows a cystic mass (*top arrow*) with several components adjacent to the head of the pancreas and adrenal gland (*lower arrow*). The infectious agent proved to be *Echinococcus*. (Printed with permission of Dr. Elmar Merkel, Cleveland, Ohio.)

manifestations, the many locations in which they can appear, and the many complications with which they can be associated.^{20, 26, 29} The location and size of the cyst can produce symptoms and problems for the patient, but the complications can be life-threatening. With prompt, adequate treatment, most pseudocysts can be managed effectively.

Symptoms associated with pseudocysts depend on the amount and severity of pancreatitis and the size and speed of their growth. Patients may experience significant, ill-defined pain associated with pancreatitis and have small pseudocysts. Large pseudocysts can cause pain secondary to the inflammatory process, displacement of or effect on adjacent structures, or the amount of pressure within the pseudocysts.

Some patients show an evolution of pseudocysts on sequential examinations, first having a large amount of edema in the area of the pancreas, which usually obscures the margin of the gland and extends into various adjacent areas. As the inflammation resolves, the fluid may coalesce into a well-defined pseudocyst with a clearly defined wall (Fig. 38-67). In other patients, the pseudocyst appears to evolve from necrosis within the pancreas. The necrosis begins as a subtle area of low density and progresses to a well-defined cavity.

Figure 38-67. A, CT scan taken early in the patient's disease shows mild edema around the gland. B, Later scan shows increased edema between the head of the pancreas and the stomach. C, After a number of days, the inflammatory fluid coalesced into a pseudocyst (*arrow*).

Figure 38-68. Typical appearance of a pseudocyst (p) in the head of the pancreas. Also note dilated pancreatic duct (arrow).

The administration of intravenous urographic contrast material enhances the margins of such collections and makes the central portion appear less dense. Because of the high protein content of such pseudocysts, the density may appear high, and the appreciation of the cystic nature of a lesion may not be apparent without the use of intravenous contrast material.

Anatomic Location

Pseudocysts are typically located in the pancreas and the immediate peripancreatic region. They can be associated with other severe or minimal findings of pancreatitis (Figs. 38-68 and 38-69). In some cases, however, pseudocysts may extend to more remote anatomic areas, by dissection along or through fascial planes, along areolar tissue around vessels (intermesenteric space according to a

new concept of retroperitoneum; see Chapter 43), through capsules, or into the substance of solid organs.

The omental bursa is the second most common location of pseudocysts, according to Siegelman and associates.²³⁰ The inflammation causes closure of Winslow's foramen, and the fluid fills the entire omental bursa or is confined to a local region of the bursa.¹⁴⁰

When located in the inferior portion of the omental bursa, pseudocysts produce anterior displacement of the body and antrum of the stomach. When located in the splenic portion of the inferior recess, they produce anterior displacement of the fundus (Fig. 38-70A and B). Those extending into the superior medial recess of the lesser sac lie adjacent to the caudate lobe of the liver (see Fig. 38-55). In such cases, it is important to use oral contrast material or the decubitus position because the pseudocyst otherwise can be mistaken for fluid-filled stomach or duodenum.

If the patient is too ill for these technique modifications, a large pseudocyst might be confused for the distended fundus of the stomach.¹⁷² If adequate intravenous contrast material is given, the gastric wall enhances, permitting distinction from the wall of the pseudocyst. Pseudocysts located in the splenic recess may reveal themselves by producing a circular interface with the air in the stomach rather than the normal level air-fluid interface (bezoar, retained food, or gastric mass may give a similar appearance) (Fig. 38-70B).

If a pseudocyst is large and aggressive, it may erode from the lesser bursa into adjacent contiguous areas. Extending inferiorly, it may split the leaves of the omentum, producing a mass that projects below the surface of the stomach in an anterior position (Fig. 38-71). The inflammatory fluid may also digest through the lining of the omental bursa and dissect into the hepatogastric ligament and even beneath the capsule of the liver (Fig. 38-72A) or spleen (Fig. 38-72B). A pseudocyst may also proceed cephalad from the superior medial recess next to the caudate lobe into the posterior mediastinum¹⁹¹ adjacent to the esophagus (see Fig. 38-55).

Figure 38-69. A, Small pseudocyst in the uncinate portion of the pancreas (arrow), on a CT scan obtained on multislice scanner. B, Coronal reconstruction shows pseudocyst (P) in lower uncinate process. The dilated major (vertical arrow) and minor pancreatic ducts (horizontal arrow) are above the cyst, which is also medial to the second portion of the duodenum (curved arrow).

Figure 38-70. A, Small pseudocyst (P) in splenic portion of inferior portion of the lesser sac (arrow) is visible effacing the posterior surface of the stomach fundus. Note the thickening of the gastric wall (left curved arrow) and the dilated varices in and adjacent to the wall of the stomach (right curved arrows). Even the mucosa of the stomach is enhancing remarkably. B, Very large pseudocysts on the posterior surface of the stomach can give the deceptive appearance of a dilated stomach fundus, unless appropriate oral and intravenous contrast agent is used. For many patients undergoing this examination, the “NPO” status precludes the use of oral contrast material. With use of intravenous contrast material, the anterior surface of the pseudocyst effacing the gastric mucosa (arrow) can be recognized.

As with the spread of material during the acute inflammatory phase, a pseudocyst may develop or digest through fascia^{96, 210} and capsules directly into a solid organ. This may occur in the spleen (Fig. 38-72B), liver, or kidney (Fig. 38-73). Such pseudocysts can be diagnosed from knowledge of the patient's history or through a search for signs of pancreatitis, but in many instances, diagnostic aspiration is required, as suggested by Baker and coworkers.¹²

Figure 38-71. Pseudocyst (arrows) dissecting into greater omentum and extending caudally below the level of the stomach. At this location, such cysts appear to be in the peritoneum, but they are enclosed by the surfaces of the greater omentum.

Resolution

Pseudocysts may spontaneously resolve simply from resorption of fluid or drainage into a loop of bowel. Both mechanisms are commonly observed. When evacuation into bowel occurs, residual gas may be seen in the cyst or a small pathway between the cyst and the bowel loop (Fig. 38-74).

Beebe and colleagues²⁰ found that pseudocysts less than 4 cm in diameter were more likely to resolve spontaneously than larger pseudocysts. Kolars and colleagues¹³⁵ found that the outcome and recurrence of pseudocysts did not depend on their size, multiplicity, anatomic location, or communication with the pancreatic duct.

Complications

Pseudocysts must be treated to avoid a number of severe complications. Pseudocysts can rupture into the peritoneum or a loop of bowel. Rupture into the peritoneum can be catastrophic, producing a generalized chemical peritonitis (Fig. 38-75). Rupture into a loop of bowel can be catastrophic or curative. The outcome probably depends on the loop of bowel that is entered, the degree of bacterial colonization, and the immune competence of the patient. Rupture into colon is potentially more threatening than rupture into other bowel because of the nature of the gram-negative flora. The patient with an incompetent immune system or an overwhelming bacterial inoculum may succumb if prompt, effective treatment is not given.

Finally, hemorrhage can occur in association with a pseudocyst and can produce life-threatening loss of blood. Such bleeding may simply be from the inflamed wall, or pseudoaneurysms may occur in the wall as a result of enzymatic digestion (Figs. 38-76 and 38-77).

Figure 38-72. A, CT scan taken at a high level shows cystic fluid in the subcapsular region of the liver (*arrow*), the porta hepatis (*curved arrow*), and the retroperitoneum behind the right kidney (*horizontal arrow*). B, Scan taken at a slightly different level shows inflammatory fluid around the spleen (*vertical arrow*) and bare area of the liver (*horizontal arrow*) by the adrenal gland.

Figure 38-73. Pseudocysts may cross the fascia into the perirenal space. This scan shows a large pseudocyst (*arrow*) in the perirenal space on the left side.

Figure 38-74. A, Large retroperitoneal pseudocyst (C) around the vena cava (*arrow*), which is located behind the duodenal bulb (B). B, Follow-up study shows an "empty pseudocyst" containing air (*arrow*) beside the bulb (B). Note the normal size of the vena cava.

Figure 38-75. A, CT scan showing a large fluid collection in the left side of abdomen after rupture of a pseudocyst. B, Scan showing small gas bubble (*arrow*) within fluid collection in the pancreatic bed; aspiration subsequently showed this area to be infected.

Figure 38-76. A, Axial CT scan shows enhancing focus in the head of the pancreas (*straight arrow*) posterior to the portal vein coursing toward the porta hepatis region. It is located in an inflammatory mass (*curved arrows*). Note the severely dilated pancreatic duct (D). B, Traditional angiogram shows “pooling” of contrast material in a pseudoaneurysm (*arrows*).

Figure 38-77. CT scan in a patient with polycystic disease of the kidneys shows massively enlarged kidneys with many cysts. Blood density mass is seen in the head of the pancreas, representing hemorrhage into a small pseudocyst (*arrows*).

Figure 38-78. A, A very large pseudocyst is visible in the body and tail of the pancreas. B, Repeat scan of the same pseudocyst shows multiple pockets of gas (arrows), which represent infection with a gas-forming organism.

Pseudocysts with Air: Abscess or Fistula

Gas in pseudocysts suggests the following possibilities: (1) fistula formation, (2) gas-forming infection (Fig 38-78), (3) surgically produced internal cystotomy (Fig. 38-79), and (4) any combination of these three.

Several reports in the literature provide useful insights into gas in pseudocysts. Torres and colleagues,²⁵⁶ Alexander and coworkers,³ and Petruschak and associates¹⁹⁹ have reported seeing gas in pseudocysts from gastrointestinal fistulas (Fig. 38-79). A common observation is that patients who have gas in pseudocysts should be evaluated to determine the type, size, and nature of the fistula. In some patients, the fistula can be found by radiologic methods before surgery, but in other patients it may be detectable only at surgery.

Depending on the site of the fistula, treatment may be

easy or difficult. In most patients, a traditional bowel study using a water-soluble iodinated contrast agent or a barium sulfate contrast suffices (i.e., upper or lower study). In other patients, it may be helpful to perform a percutaneous aspiration for a diagnostic sample, drainage, or sinogram.

Fistulas occurring in the stomach or duodenum may drain a pseudocyst effectively (see Fig. 38-74), and surgical intervention may not be needed. In patients who have fistulas in the colon, the prognosis is not so good, because colonic pathogens are more likely to cause serious infections and sequelae; the traditional surgical method requires immediate débridement and bowel diversion in this case. The circumstances of each patient must be considered, however, because rarely, a patient may tolerate a colonic fistula and not require surgery. The following factors determine the outcome of such a problem: the immune status of the patient, the size and nature of the fistula, the size of

Figure 38-79. A, Appropriate surgery for pseudocysts is gastrocystotomy. CT scan shows fluid-filled and air-filled cavity (arrow) behind the stomach. B, Subsequent scan shows contrast material (arrow) filling the cyst cavity, indicating the nature of the cavity and communication with the stomach. Note the high-density suture line between the stomach and cyst.

the inoculum, and the virulence of the pathogens. Healthy immunocompetent patients may tolerate such events well, and immunocompromised patients may not.

Vascular Problems

Pancreatitis and pseudocysts can cause a number of vascular problems, including vascular occlusion, pseudoaneurysms, and spontaneous hemorrhage.

Occlusion of many vessels, but most commonly the splenic vein and artery, can occur. In such cases, only the secondary effects, such as varix formation or shrinkage of the spleen, may be seen.

Pseudoaneurysms occur in pancreatitis in 10% of patients as a result of enzymatic digestion of the vessel wall. Proper diagnosis and treatment are important because hemorrhage is associated with bleeding 37% of the time.^{24, 194, 245} Pseudoaneurysms can occur in any vessel in the peripancreatic area, but the most common vessel is the splenic, followed by the gastroduodenal¹⁷⁸ and branches of the pancreaticoduodenal arteries.^{31, 33, 238} In some patients, diagnosis of a pseudoaneurysm is not made prospectively, but the patients have acute hemorrhage associated with a pseudocyst.

Sometimes a clearly definable pseudoaneurysm in the area of the pancreas can be confused with a pseudocyst.^{149, 228} Careful scrutiny of the CT scan shows a circular area of low density, which may correspond to a clot within the aneurysm. Because of the potential for such pseudoaneurysms, it is imperative that a dynamic intravenous study be performed before any interventional procedure²⁶ (see Fig. 38-76; Fig. 38-80).

Natural History of Pseudocysts

The natural history of undisturbed pseudocysts has been extensively studied by several authors,¹²⁹ including Bradley and others^{28, 29} and Pollack and associates.²⁰⁷ In Bradley's series, 54 patients had serial studies over many months; the authors were able to follow the outcomes accurately.

Of 54 patients who had serial, clinical, and sonographic evaluations, 10 (or 40%) had spontaneous resolution.²⁹ Five

(20%) experienced complications, including abscess, rupture, and biliary obstruction. In patients with pseudocysts lasting 7 to 12 weeks, the proportion of spontaneous resolutions and the frequency of complications remained constant at 46% (6 of 13 cases). Spontaneous resolution did not occur in 12 patients observed between weeks 13 and 18, but the rate of complication increased to 75% (8 of 12 cases). These complications included spontaneous rupture in five patients, secondary infection in one, obstructive jaundice with sepsis in another, and a spontaneous cystogastric fistula in another. This last patient died after massive gastrointestinal hemorrhage. Of five patients studied for more than 19 weeks, three had complications and two did not complete follow-up. Seven deaths occurred as a direct result of the pseudocyst, and complications occurred on an average of 13.5 weeks after initial development.

In another study, by Pollack and associates,²⁰⁷ similar findings were noted in a group of 54 patients. The authors treated patients with nonoperative means until sepsis occurred or until the pseudocyst had persisted more than 3 weeks. They reported that 29 patients underwent elective surgery during the initial hospitalization, and 6 patients who did not undergo surgery had abscesses and died.

Surgical Treatment

Good information exists on selected surgical treatment based on pseudocyst evolution. Bradley and others^{28, 29} and Bodurtha and colleagues²⁶ have recommended that surgical intervention not be performed in the first 6 weeks because of the high incidence of spontaneous resolution. Furthermore, they recommend that treatment be deferred during this time because the inflammation usually does not have a well-defined fibrous wall that could hold the sutures required for a cystogastrostomy. In such cases, external instead of internal drainage would be required. External drainage has a high rate of infections, fistulas, and complications. Between 6 and 13 weeks, the pseudocyst wall becomes well defined; thus internal drainage is possible. If a pseudocyst is well defined and has a thick fibrous wall, internal drainage by cystotomy is the preferred method of treatment because it has the greatest success rate and the lowest complication and recurrence rates. Waiting longer

Figure 38-80. A, CT scan shows a low-density mass (A) with a central, high-density region (arrow) that represents a pseudoaneurysm of the splenic artery. B, Angiogram shows the large pseudoaneurysm (A) coming from the splenic artery.

than 13 weeks creates a greater risk for spontaneous complications.

As one might anticipate, development of radiologic procedures paralleled the surgical experience. Initial methods of external drainage were used with some success, but these methods had problems similar to the surgical ones. More recently, certain radiologic methods have had some success.

Imaging Follow-up of Internal Drainage

Patients who undergo an internal drainage procedure show a consistent pattern of resolution on CT scan. Initially the pseudocyst appears as a total fluid density, but immediately after surgery it contains air. As long as patency with the bowel exists, such cysts fill with gastrointestinal contrast material. With further resolution, the amount of air and fluid lessens (see Figs. 38–64 and 38–79). In patients who do not show prompt resolution, abscess due to colonized bacteria that have sequestered a portion of the pseudocyst should be suspected.

Chronic Pancreatitis

Once the acute phase of pancreatitis has resolved, the pancreas may return to normal. Chronic changes may occur, however, resulting in persistent or permanent alterations in the pancreatic function or morphologic features.

Pathologically, fibrosis and scarring may alter the morphologic characteristics and density of the parenchyma and duct system.¹⁶⁶ The entire gland may be affected, but only a focal area may be involved. Focal changes may occur in the acinar or ductal portions and may involve the deposit of calcium salts.

Clinically, the patient may have chronic symptoms such as upper abdominal pain, back pain, and steatorrhea, diabetes, or recurrent inflammation. Diagnosis of chronic pancreatitis is important because a plausible explanation for a number of clinical signs can be given if its presence can

Figure 38–82. Axial CT scan shows that the head (*h*) of the pancreas is normal but the body and tail are atrophied. Also note that chronic infection has produced thickening of the lateroconal fascia (*straight arrow*) and the perirenal fascia, both anterior and posterior (*curved arrows*).

be documented on scanning. Furthermore, a more definite statement about the presence of new findings can be made if it is known that a patient previously had pancreatitis. In such cases, comparison scans are important.

Diagnostic Signs

In chronic pancreatitis, the overall size of the gland may be normal, enlarged, or reduced, depending on the amount of fibrosis or atrophy, and the level of activity of the inflammation.⁶⁰ Atrophy or reduction of the size of the gland, like enlargement, can occur in either a diffuse or focal fashion (Fig. 38–81). In addition to these findings, the thickening of the renal fascia, which is seen in the acute form of the disease, may become chronic (Fig. 38–82). Chronic fibrosis can produce loss of the fat plane

Figure 38–81. A, CT scan shows low density with atrophy of two portions of the pancreas (*arrows*). B, Chronic inflammation may result in complete atrophy of the glandular elements so that the only residual is a faint pattern of the ductal system (*arrow*).

Figure 38–83. Deposition of calcium is the best indicator of chronicity. Scan shows fine calcifications scattered throughout all portions of the gland.

around the vessels and can be mistaken for tumor encasement.^{11, 116, 158} Chronic pancreatitis is usually associated with intermittent episodes of recurrent inflammation, which can produce alterations in the baseline appearance of a diseased gland.

Acute edema and swelling may be superimposed on the fibrotic gland and may fluctuate with the activity of the disease. With resolution of the acute process, follow-up studies show a return to the baseline appearance. If the mass does not diminish or if it increases in size, a coexisting neoplasm must be considered. A percutaneous biopsy should be performed. If the biopsy result is negative and follow-up studies show no definite progress, one can accept the premise that the chronic inflammation is establishing a new baseline with an increased size.

Calcifications. The hallmark of chronic inflammation is the deposition of calcium.^{220, 260} With inflammation and

necrosis in the pancreas, the local chemical changes produce the deposit of calcium carbonate and calcium phosphate. The deposit of calcium salts can vary in location and amount. Most commonly, calcification first occurs in the head, but with continued inflammation, calcification occurs in the body and tail. Calcifications can occur within the parenchymal or ductal portions; either area can be involved first (Fig. 38–83). It is important to note whether the duct is involved, because various surgeons believe that relieving pancreatic duct obstruction may be beneficial to some patients.

Although the typical pattern is one of progressive deposit, it is possible to observe the reverse—decalcification⁷ (Fig. 38–84). This is a rare phenomenon, but it has been observed on plain radiographs as well as CT scans. Initially, decalcification was thought to indicate the development of a neoplasm, but researchers have refuted this point. To our knowledge, decalcification is neither good nor bad. One should not mistake the change in configuration for calcification that can occur with changes in size of the gland (Fig. 38–85).

CT is the most sensitive of all radiographic procedures for detection and accurate localization of calcifications. A number of processes other than inflammation can produce calcifications, and some materials can simulate calcium. First, a variety of tumors produce calcifications in a large percentage of cases (see section on tumors). Second, the most common entity producing calcification in this area is probably arteriosclerotic changes in vessels or aneurysms. Finally, foreign bodies (swallowed objects, surgical sutures, catheters, or other devices) and iron-filled lymph nodes in hemochromatosis appear opaque and simulate calcification.

Pancreatic Duct. The changes that occur in the pancreatic duct are discussed earlier. In summary, one can make some statement about the probability of malignancy or inflammation from the size and the configuration; but these relationships are not absolute. The factors depend on the benign or malignant nature of the process and the duration or completeness of the obstruction (Fig. 38–86).

Frequency of Signs in Chronic Disease. The frequency of inflammatory signs in pancreatitis has been ex-

Figure 38–84. A, Decalcification can occur rarely. This early CT scan shows dense calcium deposits within the head. B, Later scan demonstrates that the overall size of the gland has not changed but the density of the anterior calcification (arrowhead) has decreased owing to decalcification.

Figure 38-85. A, CT scan obtained before resumption of inflammation shows dense calcification within the head of the gland. B, Subsequent scan shows enlargement of the head of the gland, demonstrating that the calcifications have moved peripherally as the gland has enlarged.

tensively studied, but one of the better reviews of the findings related to chronic pancreatitis was by Luetmer and others.^{158, 159} They studied 56 consecutive patients with documented pancreatitis and without surgical intervention, in whom contrast-enhanced CT scans were obtained. Dilatation of the pancreatic duct was seen in 68% of the cases, pancreatic atrophy in 54%, pancreatic calcifications in 50%, fluid collections in 30%, focal enlargement in 30%, biliary dilatation in 29%, and fascial plane or perivascular fat changes in 16%. Although there has been some variation among the various reports as to the frequency of these signs, the constellations of findings are all similar.

Trauma

Pancreatic trauma is common in patients with injury to the abdomen. The most common types of injury are contusion, tear, and damage to the duct; late sequelae include pseudocysts, abscesses, and fistulas. Because CT is a commonly used tool for early evaluation of abdominal injury, it is important to become familiar with its usefulness and limitations.^{114-118, 204}

The largest evaluation of the pancreas by CT was by Jeffrey and others.¹¹⁵⁻¹¹⁸ In 13 cases, they found that CT was helpful for detecting some injury to the pancreas but was limited in determining the exact nature or extent of the problem (Fig. 38-87). They observed nonspecific thickening of the left anterior renal fascia in 8 of 11 cases. They were able to identify fracture or laceration of the gland in some cases, but the actual planes were not easy to visualize. ERCP is indicated if there is significant injury to the gland.

After acute injury to the pancreas and formation of a fluid collection with or without secondary infection, CT is well suited to detect and determine the extent of any such process (Fig. 38-88).

Miscellaneous Disorders

Hereditary Pancreatitis

Hereditary pancreatitis is relapsing pancreatitis among multiple family members. The symptoms, signs, and patho-

Figure 38-86. Ductal dilatation in body of pancreas with single calculus (arrow) in the main duct.

Figure 38-87. Axial CT scan shows transection (arrow) of the pancreas in the area of the neck. Note the difference in density of the body and tail compared with the head, indicating decreased vascular enhancement and edema. Also, there is a large amount of free fluid (F).

Figure 38-88. CT scan showing a large pseudocyst, which has developed after a severe injury to the gland.

Figure 38-90. Some patients with iron overload have increased density of lymph nodes (*arrow*) in the peripancreatic area and not in the gland (*open arrow*).

physiologic process of this type of pancreatitis are no different from those of the other types of pancreatitis discussed. It has been suggested but not proved that factors such as hyperlipidemia, hypercalcemia, and alcohol consumption may play a role in this disease. There are, however, two unique traits of the disease. The onset is typically in children around the age of 10 years, and there are usually calcifications within the gland in both the parenchyma and the duct system.^{17, 222, 236} Reportedly, calcification occurs more commonly in the duct system than in the parenchyma.

The majority of the patients seen with hereditary pancreatitis have been children. In our experience, calcifications occurred in the parenchymal portion as much as in the ductal portion (Fig. 38-89). They are the same types of inflammation and pseudocysts seen with adults. The best treatment has been obtained with pancreatectomy.

Hemochromatosis

Hemochromatosis results from excessive accumulation of iron in the body. The disease has a primary form, which is idiopathic, and a secondary form, which results from ingestion of exogenous iron or from multiple transfusions.⁵⁷

Figure 38-89. Hereditary pancreatitis produces calcifications (*arrow*) in the pancreas of this 6-year-old child.

CT characteristically shows an increased density in the pancreas and adjacent peripancreatic lymph nodes; similar findings have been reported by Long and associates¹⁵⁶ and Mitnick and colleagues.¹⁷⁹ Long and associates¹⁵⁶ did not find a correlation between the amount of increased density and the pancreatic dysfunction or insufficiency. Dense nodes in the porta hepatis and peripancreatic, periaortic, and perisplenic nodes should be noted (Fig. 38-90). These findings should not be confused with calcifications. Unopacified vessels may give the spurious impression of a low-density mass in the pancreas in some cases. The use of intravenous contrast material eliminates any question of a possible mass (Fig. 38-91).

Cystic Fibrosis

Cystic fibrosis, or *mucoviscidosis*, is a hereditary generalized disease affecting all mucus-producing exocrine glands of the body. The disease results in abnormally thick secretions that obstruct most exocrine glands, including the pancreas. Studies have shown that there is a greater concentration of protein in the pancreatic fluids, which may account for increased viscosity. It is postulated that inspissation of the material can produce ductal ectasia. A variety of changes can result in varied clinical situations with a wide range of findings on CT scan.

Most patients with cystic fibrosis have problems that are associated with exocrine function. The gland usually appears completely replaced with fat (Fig. 38-92). Presumably, the gland has complete and long-term obstruction, resulting in complete atrophy of the acinar portions. The islet cells are not usually affected, and the endocrine functions remain intact, without development of diabetes or other problems. This process would seem to parallel studies with laboratory animals, that show complete autolysis and atrophy of the gland when the duct is ligated; the function of the islet cells is typically not affected.

Also reported and considered to be a different entity along the same spectrum is cystosis of the pancreas.^{101, 201} Although this is an uncommon disorder, a number of large cysts scattered throughout the course of the pancreas can be observed. The cysts are typically thin walled and cannot

Figure 38-91. A, In this patient with iron overload, there is increased density of the gland (*p*) and not the portal vein (*arrow*). The vessels should not be mistaken for an intrapancreatic tumor. B, After intravenous contrast administration, the vessels are opacified, dispelling the question of a tumor.

be distinguished from pseudocysts (Fig. 38-93). In some patients, lesser variations are seen, which include presence of a fluid-filled duct or smaller cysts. The fluid has calcium and eosinophilic concretions. The fluid is said to be antigenically identical to serum and contains increased amounts of inactive trypsinogen; this finding indicates that autodigestion has no major role in the process.

In another group of patients with a mild form of cystic fibrosis, the exocrine function of the gland may be preserved with or without any pulmonary symptoms. Patients with pulmonary problems who have a normal-appearing pancreas and no associated abdominal problems have been observed. Other patients who do not suffer from pancreatic insufficiency may experience recurrent, severe pancreatitis. The incidence of pancreatitis is said to be approximately 0.05% of all patients. Pancreatitis may develop in some patients who have a mild but undiagnosed form of cystic fibrosis without pulmonary symptoms. Masaryk and Achkar¹⁶⁹ reported several patients with active clinical pancreatitis thought to originate from functional obstruction of the pancreatic duct. The diagnosis of cystic fibrosis had not even been considered until pancreatitis occurred. Although

these authors did not postulate the etiologic conditions, it seems logical to assume that inspissated pancreatic fluid creates partial obstruction of the duct. It is not sufficient to destroy the acinar portion but is sufficient to impair flow, producing inflammation.

Fatty Pancreas

A fat-density pancreas can be entirely normal (see section on normal variations), but a number of entities have been reported to produce fat replacement of the gland.¹⁹⁸ These include pancreatic duct obstruction, malnutrition, Shwachman's syndrome, hemochromatosis, viral infection, Cushing's syndrome, steroid therapy, and an unusual entity called lipomatous pseudohypertrophy of the pancreas. Specific reports on these entities have not yet appeared, but one would anticipate future reports on this topic.

Benign Tumors

Fatty Tumors

See Figure 38-94 for cases in which CT revealed fatty masses of the pancreas.

Figure 38-92. Typically, in patients with cystic fibrosis who have pancreatic atrophy, the pancreas (*arrowhead*) is completely replaced with fat.

Figure 38-93. Rarely, cystic fibrosis produces a massive cyst formation of residual ducts (*D*), which are occluded. Such changes have been called *cystosis*.

Figure 38-94. A, CT scan in a 45-year-old man after a motor vehicle collision. The patient sustained multiple pelvic fractures and serious cranial injuries. Contrast-enhanced CT scan shows incidental 3 × 4-cm fatty mass in pancreatic head. B, CT scan in a 47-year-old man admitted after several days of nausea, vomiting, and diffuse epigastric pain radiating to the back. The patient had history of multiple hospitalizations for abdominal pain. (This type of appearance has been described as *lipomatous pseudohypertrophy*.) C, CT scan in a 36-year-old woman after resection of liposarcoma that involved the pancreatic body and tail. The patient had undergone wide resection relatively recently, with splenectomy, left nephrectomy, and distal pancreatectomy. Contrast-enhanced CT scan shows large, recurrent liposarcoma adjacent to residual pancreas. Note the foci of fat in the mass. At surgery, the mass was adherent to residual, density and intermediate density, represents liposarcoma. (From Katz et al., AJR, Feb. 1999.)

Cysts

True cysts of the pancreas differ from pseudocysts and retention cysts through origin, histologic appearance, and clinical significance. True cysts are believed to be anomalously developed from remnants of the embryologic ductal systems. Histologically, they may have a lining of epithelial cells, but with pressure changes the lining may atrophy. In such cases, the wall may consist of smooth, fibrous tissue. Rarely, cysts may be complicated by infection or hemorrhage (although not with the frequency of pseudocysts).

They can appear incidentally but most commonly occur with multicystic²²⁷ or von Hippel-Lindau disease. Levine and associates¹⁵¹ reported on 31 patients with a history of von Hippel-Lindau disease. Five of the patients had pancreatic cysts. The CT appearance of this entity is identical to that of any other well-defined cystic abnormality (Fig. 38-95).

Lymphangioma

A single case of lymphangioma of the pancreas has been reported.¹⁹³ CT scan demonstrated a "cystic" mass that was indistinguishable from a cystadenoma; the diagnosis can be made only on pathologic analysis.

Adenomas

A number of benign solid tumors, some of ductal origin and some of acinar cell origin, do occur, but no specific reports have appeared in the literature. We have encountered one case of adenoma of the pancreas that was palpated and examined by biopsy at surgery but did not show any morphologic or density changes on CT scan that would distinguish it from a neoplasm (Fig. 38-96). Further experi-

Figure 38-95. True cysts of the pancreas (arrow) may occur with polycystic disease.

Figure 38-96. Adenoma of the head of the pancreas (A).

ence must be reported before any generalizations of the CT appearance of adenoma can be made.

Von Hippel-Lindau Disease

Von Hippel-Lindau disease is a hereditary disease with a dominant trait. It can be associated with a number of abnormalities, including angiomas of the central nervous system and eye as well as neoplasms and cysts of the pancreas, kidney, adrenal glands, and epididymis.

Pancreatic involvement by this disease consists of cysts, serous cystadenomas, solid nonfunctional islet cell tumors, and adenocarcinomas. The earliest signs are said to be small cysts, but calcifications are common. Progression of the disease can result in steatorrhea and diabetes. Solid tumors usually represent nonfunctional islet cell tumors or adenocarcinoma.

Periodic monitoring of diagnosed patients and screening for the disease in unaffected family members are appropriate. This approach enables genetic counseling for family planning. Also, early detection of problems with high morbidity and mortality can permit earlier effective treatment.

Levine and associates¹⁵¹ and Choyke and colleagues⁴² have reported on screening of visceral problems. Choyke and colleagues found CT to be more accurate than MRI and ultrasonography. CT detected all pancreatic and renal abnormalities in a group of 14 patients, whereas ultrasonography and MRI each missed abnormalities in three cases, including two pancreatic masses that were seen only on CT.

The recommended screening modality depends on the age of the patient. Choyke and colleagues⁴² recommended ultrasonography and MRI for evaluation of the abdomen and central nervous system in patients younger than 11 years. Contrast-enhanced CT was recommended for patients older than 16 years.

Vascular Abnormalities

Because the pancreas lies in a location surrounded by vascular structures, a number of vascular entities occur in the region and can be associated or confused with patho-

logic conditions of the pancreas. Abnormalities can be related to inflammatory, arteriosclerotic, or neoplastic involvement of the vessels.

Splenic Artery Aneurysms and Pseudoaneurysms

Splenic artery aneurysms are common and characteristic. Surgical repair of such aneurysms is required only when they are more than 3 cm in diameter or if they occur in women who are of child-bearing age or are taking oral contraceptives. This latter group is at risk for spontaneous rupture. The aneurysms appear as circular soft tissue densities or curvilinear calcification in the area of the splenic artery (Fig. 38-97). On some occasions, when there is no extensive calcification of the aneurysm, it may simulate a focal mass. Aneurysms can be definitively diagnosed only on a dynamic bolus scan or with an infusion of contrast material at a high rate (Fig. 38-98). Identification is important because of the possibility that they can be mistaken for a mass in the gland. Spontaneous hemorrhage into the pancreatic duct has been reported with a splenic aneurysm.

Other Aneurysms

Aneurysms in the peripancreatic vessels can occur based on arteriosclerotic disease, but they are rare anomalies. They most commonly contain calcifications, and the diagnosis is best made with dynamic bolus scanning. Historically, these vessels are likely to rupture, so most authors recommend surgical correction in the appropriate patients. The aneurysms may be seen in the gastroduodenal, hepatic, or other vessels.

Hepatic Artery Aneurysms. Hepatic artery aneurysms represent 19% of splanchnic aneurysms and are atherosclerotic, traumatic, or mycotic. Surgical treatment is recommended because 44% of such aneurysms rupture. Therapy consists of ligation of aneurysmectomy; the extensive collateral network provides an adequate blood supply.

Figure 38-97. Aneurysms of the hepatic artery and splenic artery may demonstrate calcified dilatations, as noted in this case (arrows).

Figure 38-98. A, Although the patient was referred because of suspected tumor, the correct diagnosis of noncalcified splenic artery aneurysm was made preoperatively. CT scan with bolus dynamic contrast injection shows a high-density mass (A) in the area of the splenic pedicle, suggestive of an aneurysm. Digital subtraction angiography (DSA) was performed to document it. B, DSA shows the large aneurysm.

On CT, a hepatic artery aneurysm is a mass of blood density that enhances with bolus injection of contrast material. It may be adjacent to the artery or peripheral in the liver (Fig. 38-99).

Superior Mesenteric Artery Aneurysms. Superior mesenteric artery aneurysms are the third most common splanchnic aneurysms, of which 63% are mycotic lesions, and most are associated with endocarditis on the left side. Most other causes are secondary to medial degenerative disease. Operative treatment is justified because of the common occurrence of rupture or arterial occlusion (Fig. 38-100).

Celiac Artery Aneurysms. Celiac artery aneurysms are uncommon and are mainly atherosclerotic in origin. Approximately 20% rupture. Surgical treatment is recommended and consists of resection or ligation.

Cavernous Transformation of the Portal Vein

Cavernous transformation of the portal vein is a vascular anomaly that consists of multiple venous collaterals in

the area of the portal vein. The incidence is small, and only one series of 16 cases has been reported, by Mathieu and coworkers.¹⁷⁰ Although it was once thought to be a congenital problem, it is now thought to result from portal vein occlusion or compromise. Because the numerous vascular channels can occur in any portion of the porta hepatis, a network of vascular channels adjacent to the pancreatic head can simulate a pancreatic mass. Correct diagnosis depends, of course, on familiarity with the entity and an appropriate scanning technique, which includes ample enhancement with an intravenous contrast agent.

The correct diagnosis can be easily made if the channels are large and the dynamic bolus scan has been administered properly (Fig. 38-101A). Diagnosis is more difficult when the vascular channels are not as well formed, are smaller, and are located in the area of the portal vein. In such cases, the diagnosis can sometimes be suggested by the presence of small amounts of fat irregularly interspersed within the porta hepatis region. It is very difficult to distinguish from another unusual entity, such as an arteriovenous malformation of the pancreas (Fig. 38-101B). In difficult cases, an angiogram may be required. In our early experience, before we were familiar with the appearance of this entity, we

Figure 38-99. Massive aneurysms or pseudoaneurysms may simulate fluid-density pseudocysts. Note the large area of low-density clot surrounding the small area of high density, representing flowing blood in this large aneurysm.

Figure 38-100. A, Axial CT scan shows circular calcium density (*arrow*), representing an aneurysm of superior mesenteric artery, to the left of the superior mesenteric vein (*curved arrow*). B, Angiogram shows large aneurysm with "neck" (*arrow*) coming from the superior mesenteric artery.

Figure 38-101. A, Mass in the head of the pancreas shows increased enhancement with contrast material, a finding consistent with a cavernous transformation of the portal vein. B, Enhancing mass in the head of the pancreas, representing arteriovenous malformation of the head (*arrows*).

inadvertently performed biopsies using fine-needle aspiration on three patients with cavernous transformation that was producing a pseudomass in the head of the gland. No ill effects or blood loss occurred.

Portal Systemic Collaterals and Varices

Because of the close physical proximity to the pancreas and the possible effect of pancreatitis on adjacent structures, venous abnormalities of the portal vein and splenic vein are discussed. An enlarged splenic or portal vein may be visualized in cases of massive splenomegaly as a result of increased flow. Other entities, such as occlusion, thrombosis, or encasement of the splenic, superior mesenteric, or portal vein, result in portal hypertension and portal systemic collaterals (see Fig. 38–70A).^{168, 239}

When the obstruction to flow is intrahepatic, such as occurs with cirrhosis, dilatation of the portal, splenic, and other veins occurs.^{167, 171} Assessing enlargement of the portal and splenic vessels is subjective, but the appearance is usually obvious. When portal pressure has been present for long periods, calcifications may occur in the wall (Fig. 38–102).

With portal hypertension, a number of portal systemic collaterals appear.^{123, 125} A common finding in such cases is recanalization of the umbilical vein in the falciform ligament, which can feed superficial periumbilical veins that form the classic caput medusae. There is dilatation of the inferior mesenteric vein coming off the splenic vein in some patients with portal systemic collaterals. In such cases, the dilated inferior mesenteric vein courses on the left side of the aorta, down to the perirectal hemorrhoidal veins.¹⁰⁸

Large esophageal varices may be seen as a mass of serpiginous structures that enhance on bolus injection of contrast material. Systemic collaterals forming a splenorenal shunt can be well seen as enhancing tubular structures in the splenorenal ligament (see Fig. 38–70A). The collateral pathway is through small veins from the medial surface of the spleen, through the adrenal veins, and into the left renal vein. There may be a significant change in the caliber

of the vena cava above and below the renal vessels, probably because of the difference in blood flow at these two levels. We have seen these vessels persist in a patient with such a shunt, with even-flowing splenectomy. In this case, tumor was considered until a bolus-dynamic scan was performed.

The accuracy of detecting varices has not been defined, but a number of authors have discussed the CT appearances. Primary diagnosis by CT scan is probably not as good as that by endoscopy or barium swallow study, but varices should be recognized when they are present. Such information may be helpful as an additional clue for correct and complete interpretation and is a critical factor if a percutaneous interventional procedure is being considered.

If thrombosis of the veins is suspected as the primary problem, administration of contrast material for a dynamic bolus study is essential. In instances of thrombosis of the portal or mesenteric vein, clot within the vessel is visualized as a filling defect (Fig. 38–103). If the clot extends into the intrahepatic portion of the liver, it may give the spurious impression of biliary dilatation.

Malignant Tumors

In contrast to some other cancers, pancreatic carcinoma has risen in incidence in recent years. In the United States and the United Kingdom, it is now the fourth leading cause of cancer death in men and the sixth leading cause of cancer death in women. Contributing causes have not been well defined, and previous associations with pancreatitis and alcohol abuse have been disproved.¹⁵⁰ Some related factors may be smoking, high-fat diet, diabetes, industrial exposure, and perhaps coffee.

Tumors of the pancreas other than adenocarcinoma are rare, and no change in their incidence has been noted. The diagnosis of all tumors has improved as a result of laboratory, clinical, and imaging studies.

Clinical Syndromes

Several syndromes that have specific symptoms have been associated with exocrine gland tumors. The most familiar sign is the association of adenocarcinoma neoplasms with migratory thrombophlebitis, called *Trousseau's sign*. The exact cause of Trousseau's sign is not clear, but the most commonly proposed mechanism is the release of tumor proteins from necrosis that act like tissue thromboplastin material. This material triggers the normal coagulation system to form thrombi in various veins.

A somewhat characteristic perineoplastic syndrome has been associated with acinar cell carcinoma. The syndrome consists of peripheral fat necrosis, polyarthralgia, and eosinophilia. It is thought that the release of lipase and other active enzymes into the bloodstream produces digestion of fat in the marrow and other areas, causing the symptoms.

The endocrine types of islet cell tumors produce clinical syndromes related to excessive secretion of their respective products. At least eight different cell lines in the islets of Langerhans and specific syndromes related to most of these cell lines have been reported. The endocrine products caus-

Figure 38–102. Chronic portal hypertension may rarely produce calcifications in the walls of the portal vein and splenic vein (arrow), as noted in this scan.

Figure 38-103. *A*, CT scan taken at the level of the lower pancreas shows low-density filling defects in the superior mesenteric veins (arrow) to the right of the superior mesenteric artery. In such cases, the vein may be mistaken for a dilated common bile duct. Distinction can be made by following the anatomy on contiguous sections. Also, note the excessive number of venous collaterals in the peritoneal cavity (curved arrows). *B*, Scan taken at a higher level shows the large clot in the portal vein (arrow), extending toward the porta hepatis region.

ing these syndromes include insulin, glucagon, gastrin, somatostatin, and vasoactive polypeptide; the signs and symptoms are discussed later.

Nonendocrine Tumors

Pancreatic Adenocarcinoma. Ductal cell adenocarcinoma constitutes 80% of the neoplasms of the pancreas and occurs most commonly in the head (65%). It is most common in older patients and has a higher incidence among men. Patients frequently have weight loss, pain, and jaundice, but a variety of other symptoms related to the gastrointestinal tract or metastatic spread can occur.²⁶

The treatment and outcome have not significantly changed in recent years. The overall long-term results from surgery and chemotherapy have not been good, but there is reason for some optimism. With the availability of modern CT equipment, proliferation of medical information, and greater experience, two positive trends exist. At least with current technology, it has been possible to avoid surgery in patients for whom it would be inappropriate, especially since such surgery can have a high morbidity.⁸⁸⁻⁹² Similarly, because more likely candidates are undergoing surgery, it is my belief that outcome data in the future will show an improvement in survivorship. Second, several new chemotherapeutic agents have produced remarkable improvements in the short term.

Diagnostic Signs. Tumors may demonstrate one or a combination of the following diagnostic signs.^{88-92, 94, 152, 225, 240}

1. Morphologic and contour changes.
2. Mass effect.

3. Density changes (i.e., low density or calcification).
4. Contrast enhancement.
5. Pancreatic duct changes.
6. Secondary signs.

Morphologic and Contour Changes. The morphology of the normal gland is discussed in previous sections. Complete familiarity with the variations of shape and contour is important if one is to diagnose subtle pancreatic tumors. In most cases, alteration in the morphology caused by the mass is so remarkable that it is hard to discern even the normal margins of the remaining gland. In other cases, the changes may be so subtle that only careful attention to detail reveals the nature of the problem.^{35, 152}

Masses of the head of the pancreas are usually obvious because of their size, but subtleties can occur that require attention to diagnostic details (Fig. 38-104). Such masses may have smooth contours or a lobulated appearance (Figs. 38-105 to 38-107). Masses of considerable size displace adjacent structures, such as bowel and blood vessels. If aggressive local invasion occurs, the margin of the adjacent bowel can be involved, and there may be encasement of vessels, resulting in vascular compromise and formation of collateral vessels. Vessel involvement is an indicator of tumor unresectability (see later section).

When appreciation of a mass in the head is difficult, it may be helpful to note the presence of any discrepancy between the sizes of the head and the neck and tail. Although this discrepancy was initially believed to be an early sign of malignancy, a study indicates that it is simply a common appearance and does not necessarily indicate the presence of early disease.

An extensive study of morphologic changes was made by Muranaka and colleagues,¹⁸² who studied the overall

Figure 38-104. Pancreatic mass (*arrows*) in this patient is rather subtle because the contour is changed only on the medial portion of the gland. Because of the low density of the tumor and the adjacent dilatation of the pancreatic duct, the mass can be appreciated. The liver shows an increased enhancement in the left lobe (L) and low enhancement of the right lobe (R), due to reduced right portal blood flow.

size relationships of the head and body of the pancreas as well as the size and configuration of the pancreatic duct. The authors classified the body of the gland as enlarged when it exceeded 2.2 cm and atrophic when it measured less than 1.0 cm (see Table 38-1). They classified the head mass of the pancreas into four grades depending on the anteroposterior measurement: T1, 0 to 2 cm; T2, 2.1 to 4 cm; T3, 4.1 to 6.0 cm; and T4, more than 6 cm. In their series of 72 patients, there were 11 patients with T1, 14 patients with T2, 20 patients with T3, and 11 patients with T4 masses. They evaluated the size of normal and cancerous glands and assessed the ratio of the head and body to validate or refute earlier observations about size discrepancy.

Results of the study by Muranaka and colleagues¹⁸²

Figure 38-106. Low-density mass (M) of adenocarcinoma (*straight arrow*) is seen in the pancreatic head. Irregular dilatation of the pancreatic duct is seen (*curved arrows*). There is invasion of the tumor into the porta region, producing dilatation of the common bile duct (D) and the gallbladder (G).

showed that the normal gland varied in size as follows (see Fig. 38-46): The head varied between 19.8 and 29.5 cm, and the body varied between 12.1 and 21.4 cm. Although the size decreased with age, the ratio of head and body remained constant at 1.45 ± 0.03 . The ratio of the head and body in carcinoma patients was 3.4 ± 0.9 . An interesting finding in this series was that contrary to the traditional thinking that a discrepancy between the head and body can be found in small tumors, these researchers found that in more than half of the patients with small tumors, the body of the pancreas was actually larger than normal, resulting

Figure 38-105. A, A large mass in the body of the pancreas shows low density owing to lack of enhancement (*arrow*) and encasement of the splenic artery. B, 3D reconstruction of the mass shows a large mass in the midportion of the gland (*arrows*), adjacent to the vessels. *Curved arrow* indicates encasement around the celiac artery.

Figure 38-107. CT scan shows a large mass in the head of the pancreas that is encasing (*curved arrow*) the hepatic artery, originating from the celiac artery. Dilatation of the pancreatic duct is so severe that it is producing a retention cyst (*vertical arrow*). Left adrenal gland (*horizontal arrow*) is partially invaded on the medial surface.

in a ratio less than normal (between 1.0 and 1.5 cm). As the tumors increased in size, the pancreatic ratio rose as previously noted. These findings contrasted with the ratio noted in patients with inflammation. The ratio with pancreatitis was close to normal despite the large size of any mass because of concomitant enlargement of the body.

Tumors of the neck and body commonly produce enlargement of the gland and local extension to the splenic pedicle (Fig. 38-108). When a mass is immediately adja-

cent to the stomach, it may be difficult to appreciate unless there is adequate contrast material in the fundus. In such cases, it may be helpful to turn the patient to a decubitus position, which shifts the anatomy somewhat and clarifies the appearance. Although most tumors enlarge in the plane of the axial slice (i.e., anterior, posterior, right or left sides), they may grow in a cephalad-caudad direction and be difficult to identify as a pancreatic tumor.

Wittenberg and associates²⁶⁵ noted that carcinoma may appear as enlargement of almost the entire gland. They found that three or more portions of the gland (head, neck, body, and tail) were involved in 27% of cases, and they recommended that multiple biopsies might be required to differentiate between neoplastic and secondary inflammatory components.

One of the most disappointing facts is that despite the remarkable evolution of the diagnostic equipment and advanced experience level, carcinoma of the pancreas can occur without any distortion of the contour (Fig. 38-109). In such cases, the tumor may become manifest many months later.

Other Problems Simulating a Pancreatic Mass. A variety of problems can cause difficulties in interpreting a “mass” in the head of the gland. (See the section on normal variants and pseudomasses.) If the contrast material is not adequate to opacify the venous structures, a prominent portal vein, or the vena cava, an overall impression of “fullness” in the area of the pancreas may be noted. In such cases, a second study using adequate contrast material or an ultrasound examination can clarify the findings. When a mass abuts the stomach or duodenum, administration of oral contrast material and examining the patient in the decubitus position may be helpful.

On other occasions, enlargement of the caudad lobe of the liver by cirrhosis or another problem may produce the spurious finding of a “mass.” Another confusing abnor-

Figure 38-108. Tumors in the pancreatic tail. A, Patient with adenocarcinoma of the tail of the pancreas (*arrow*). Note the decreased density as well as the small calcifications in the tail. It is difficult to determine whether the calcifications are related to the tumor or to previous pancreatitis. B, Tumor in the hilum of the spleen (*straight arrow*) of a different patient has almost completely occluded the splenic artery (*small curved arrow*), which appears as a tiny vessel because of reduced blood flow. Infarction of the spleen has produced an infarct defect (D) in the spleen. Also note the small collateral arteries (*large curved arrow*) attempting to supply the spleen.

Figure 38-109. Small intraglandular tumor. *A*, CT scan performed early in the clinical course shows a subtle enlargement of the pancreatic duct and a tiny low-density area in the body (*arrowhead*). Note the normal-sized spleen (*S*). This study was not read as abnormal. *B*, Repeat CT scan months later shows a large mass in the body of the gland (*arrow*). There are numerous collateral vessels in the mesentery and enlargement of the spleen (*S*), indicating definite occlusion of the splenic vein.

malinity is enlargement of lymph nodes in the retroperitoneum adjacent to the head of the pancreas. Finally, another unusual entity that can cause an apparent mass is a partial malrotation of the duodenum. Because Treitz's ligament is in an abnormal location and the path of the bowel is redundant, the duodenum can produce a "clump" that looks like a mass. A fluid-filled duodenal diverticulum may also produce a "mass."

Density Changes. Although early scanning devices did not demonstrate many density differences between tumor and normal gland, modern CT consistently shows decreased density in almost all non-islet cell tumors with contrast enhancement. Freeny and others⁶⁴⁻⁶⁷ noted diminished density in 83% of patients with focal masses. Without the use of intravenous contrast material, many adenocarcinomas have an almost isodense appearance (compared with the rest of the gland). This low density observed on the

CT scan is thought to be due to decreased vascularity of the neoplasm compared with the normal gland (Fig. 38-110). Necrosis or low-density fluid production may be visible in many tumors with or without contrast material¹²⁶; this is common with mucinous adenocarcinomas, cystadenomas or cystadenocarcinomas, adenosquamous carcinomas, papillary adenocarcinoma, and any necrotic tumor resulting from necrosis or mucinous material.

A paradoxically unusual finding can occur in patients who have the normal variation of extensive fatty infiltration of the gland. Because the tumor does not contain the same amount of fat as seen in the parenchyma, it is higher in density than the normal gland (Fig. 38-111). Interestingly, one of the tumors we have observed became isodense with the rest of the gland after administration of a contrast agent. This is comparable to seeing lesions in a fat-density liver.

Another obvious change in the density of tumors is calcifications, which occur in a number of different tumor

Figure 38-110. *A*, Small low-density tumor (*curved arrows*) is seen in the head adjacent to a calcification from chronic pancreatitis. Note the subtle dilatation of the pancreatic duct. *B*, A scan obtained at a slightly higher level shows subtle dilatation of the duct (*arrow*) as well as dilatation of the side branches of the pancreatic duct.

Figure 38-111. A, This and the subsequent scan show the paradoxical increased density of a neoplasm compared with the normal gland. Note that the pancreatic head has a low density owing to fat infiltration (*arrowhead*). B, Slightly higher-level scan shows a higher-density mass in the head of the gland. *Arrowhead* points to the junction point with the neck and body, which is slightly atrophied and has a lower density owing to fat infiltration.

types in the de novo state. Typically, adenocarcinoma only rarely calcifies (see Fig. 38-108A), and calcium is considered typical for other unusual pancreatic tumors. The non-functioning islet cell tumor is the most common. The configuration of the calcifications is not helpful because they may vary in both amount and size. Other, rarer tumors that may also contain calcifications are mucinous adenocarcinomas, cystadenomas, cystadenocarcinomas, papillary epithelial tumors, fibromas, and glucagonomas, which are discussed later.¹⁰² Dystrophic calcifications may occur in any type of tumor after treatment if necrosis has resulted. Dastur and Lewin⁵¹ reported a case of adenocarcinoma that showed calcification in the primary tumor and metastases after chemotherapy.

Contrast Enhancement. The effects of contrast enhancement vary according to the method of contrast administration, enhancement by generalized equilibration or by dynamic bolus injection aided by mechanical injector. The optimal method, as noted previously, is enhancement with mechanical injection. With this method, the relatively decreased density of the tumor is better visualized as well as any vascular collaterals that may exist in the peripancreatic area (see Figs. 38-104 and 38-106). When contrast material has been given as a single bolus or drip infusion, it has equilibrated between the intravascular and extravascular spaces. (Experimental work indicates that it takes only a few minutes for this equilibration to occur.) Direct arterial injection through arterial catheters has been performed in specific cases and can be helpful in finding a small vascular endocrine tumor.

The importance of giving adequate contrast material was noted by Hosoki,¹⁰⁴ who discussed the benefit of dynamic bolus injection for the diagnosis of neoplasms. As others have noted, he observed that contrast material permitted better visualization of the pancreatic duct. He thought this procedure facilitated (1) correct evaluation of the tumor vascularity, allowing a differential diagnosis, (2) location of the boundary between tumor and nontumor tissue, (3) detection of small tumors, and (4) visualization of pancreatic invasion by peripancreatic tumors. He found that tumors were more likely to appear isodense compared

with the normal gland if contrast material was given as a slow bolus before the scan, whereas they appeared hypodense compared with the normal gland if rapid contrast injection was given. He also confirmed findings reported by other authors about the vascularity of cystic and islet cell tumors (see later).

Ductal Dilatation and Cyst Formation. Ductal dilatation can occur in either pancreatitis or neoplasm. Several observations based on the size and configuration of the pancreatic duct can be helpful. (See the section on the pancreatic duct.)

Dilatation occurs in patients in whom the duct is obstructed by a neoplasm. As noted earlier, visibility of the duct is improved by intravenous injection of contrast material, which highlights the density of the glandular tissue around the fluid-density duct. In most cases, dilatation of the duct is uniform, but on occasion there may be some tortuosity or beading of the duct. In unusual cases, obstruction of the duct may produce ectasia and enlargement of a localized segment, producing a retention cyst or pseudocyst distally (Fig. 38-112; also see earlier).

Biliary Obstruction. Biliary obstruction occurs with great frequency in the patient with a mass in the head of the gland. In these cases, the course of the dilated biliary system from the liver through the porta hepatis and down the length of the common bile duct should be followed,^{83, 198} and the level of the obstruction determined. In most cases, the dilatation ends just above the level of the pathologic condition (unless there are metastatic nodes in the porta hepatis) (Fig. 38-113).

The configuration of the common bile duct may have a characteristic finding that can help to distinguish between neoplastic and inflammatory narrowing of the duct. The complete details are noted in Chapter 38. In pancreatitis, sequential concentric narrowing of the distal duct occurs as it passes through the inflammatory mass. An abrupt end to the duct on sequential scans or an irregular margin of the dilated common bile duct is expected with neoplasm. These findings parallel those seen on cholangiography. The

Figure 38-112. A, Mass in the tail of the pancreas (*m*) has both solid and cystic components. The vasculature is intact. Also, there is some thickening of the fascial planes, which might suggest the presence of pancreatitis. Note the patency of the splenic artery and the mottled but homogeneous appearance of the spleen, which is due to the timing of the contrast injection. Compare this scan with that in B. B, 3D image produced on a multislice scanner shows tumor (*m*) adjacent to the hilum of the spleen (*S*), with the preservation of the vessels and the normal size of the spleen. C, Another level of the 3D reconstruction shows the mass (*m*) in the hilum as well as the intact portal vein (vertical arrow) and the superior mesenteric vein (horizontal arrow).

changes in the distal duct and duodenum can be appreciated on 3D CT reconstructions.

Local Extension. Local invasion of adjacent structures can be easy or difficult to see, depending on the nature or degree of involvement. In most instances, the margins of the contiguous anatomic structures are displaced and distorted by an extension of the soft tissue mass. In other cases, infiltration of the vascular planes around the superior mesenteric artery and vein or the portal venous system must be carefully sought. Acute obstruction of the portal system produces clinical symptoms and collateral vessels that are best seen with dynamic contrast studies.

Contiguous spread into adjacent organs occurs commonly and is obvious most of the time. The tumor extension usually follows the areolar tissue containing the vessels, lymph nodes, and lymphatic system with the various peritoneal reflections or ligaments. When the tumor invasion is subtle or there is associated inflammation, the appearance may be confused with edema, which can occur with pancreatitis.²⁵⁹ Extension may occur along the lines of the splenic hilum and the splenorenal peritoneal reflection. It can produce focal areas of neoplasm or necrosis within the spleen.

Invasion into the duodenum or stomach can cause gastric or duodenal obstruction. In most instances, displacement and massive involvement occur, but in some cases,

the infiltration can be so subtle that the bowel can be affected without any significant soft tissue mass.

Direct tumor invasion into or from the bowel can occur along the mesocolon, especially at the hepatic or splenic flexures. If a fistula to the bowel is created, gas in the tumor may produce an appearance suggestive of an abscess. The amounts may be so remarkable that distinction from an abscess or infected pseudocyst may be difficult (Fig. 38-114). Comparison studies are helpful because affected patients may be only slightly more ill when they are seen than other patients with tumors.

Spread of the tumor along the margins of the vasculature²²³ may result in narrowing or encasement of the arteries and veins (Fig. 38-115). In such cases, venous occlusion usually occurs first, and numerous venous collaterals can usually be seen in the adjacent tissues (Fig. 38-116). When occlusion of the artery is complete, it may produce vascular compromise of the involved organ, such as the spleen, which shows characteristic changes. Several authors, including Megibow and colleagues¹⁷⁴ and Itai and others,¹¹¹⁻¹¹³ have compared CT and angiography for the study of encasement of the vessels. They report that the finding of the loss of the fat plane around arteries on CT is as accurate for encasement as the angiographic finding of narrowing (Fig. 38-117).

A corollary sign of tumor invasion of the venous system is the dilatation of the posterior superior pancreaticoduode-

Figure 38-113. Scans demonstrating the remarkable benefit of the 16-slice multislice scanners. The images in both the axial scans and the 3D reconstructions are so numerous that it is very difficult to display them in the standard printed book. *A*, This scan shows an axial slice at the level of the head of the pancreas. The dilated common bile duct is noted (arrow). *B*, Higher scan shows that the biliary dilatation extends throughout the upper biliary system as well (arrows). *C*, Lower scan shows dilated biliary (arrow) and pancreatic duct (curved arrow) adjacent to the duodenum. No definite mass is identified. *D*, Oblique 3D image shows the dilated pancreatic duct (arrows) in the main part of the gland but no definite mass in the gland. *E*, Oblique 3D image at different level shows the dilated common bile duct (arrow) above the level of the duodenum but still no definite mass. *F*, A more coronal 3D scan shows the duodenum adjacent to the duct. The lower, second portion of the duodenum shows thickening of the duodenal wall (arrows) adjacent to the normal portion (N). This appearance is quite clearly consistent with the patient's proven diagnosis of villous adenocarcinoma of the duodenum.

Figure 38-114. A, Baseline scan of a patient with a tumor of the tail of the pancreas that is producing a soft tissue mass (arrow) in the hilum. B, Later scan shows "air" within the mass (arrow); the origin of the air was not known. C, Percutaneous puncture followed by injection of contrast material shows a fistula to the colon.

nal vein reported by several authors. The essence of this sign is that with occlusion of the normal anterior venous pathways by tumor, there is increased flow through the posterior pancreaticoduodenal vein, which becomes more apparent¹³ (Fig. 38-118).

Lymph Node Involvement. Lymph node involvement is common with pancreatic tumors.⁵ The first nodes to be involved are usually those around the vessels in the immediate peripancreatic and porta hepatis regions (see Fig. 38-115). Lymph channels follow the veins (see arteriogram, Fig. 38-3). Accordingly, the pancreatic lymph

nodes are located in their prospective peritoneal reflections (e.g., hepatoduodenal area, root of the mesentery). Direct spread within the areolar tissue of the peritoneal reflection also occurs.

Liver Metastases. Metastatic disease of the liver occurs frequently with adenocarcinoma and does not have a specific appearance. Metastatic foci appear low density within the enhanced liver and may be well circumscribed or diffuse.

Figure 38-115. Axial CT scan shows encasement (horizontal arrows) of the celiac artery (vertical arrow). Small lymph node is noted in the porta hepatis region (curved arrow).

Figure 38-116. Mass (m) in the head of the pancreas has interfered sufficiently with the flow of blood in the superior mesenteric vein that a clot (straight arrow) has formed. In such cases, one must be careful not to overdiagnose the findings because incorrect timing of the bolus of contrast material might produce a spurious finding owing to unopacified blood. Note the presence of associated venous varices in the mesentery, which supports the diagnosis of occlusion (curved arrows).

Figure 38-117. This set of images has been retained for historical purposes. With the advent of the new multislice devices, it is very likely such direct angiograms for diagnosis of pancreatic cancer will never be performed in the future. *A*, CT scan of pancreatic mass with encasement of the splenic artery (*large arrow*), which is producing low-density areas (*small arrows*) in the spleen. *B*, Scan taken at a later phase shows the splenic vein (*black arrow*) and collateral veins in the perisplenic area and the left gastric area (*white arrows*). *C*, Arteriogram showing encasement (*arrow*) of the origin of the splenic artery. *D*, Numerous venous collaterals in the perisplenic area (*arrow*) produced by occlusion of the splenic vein.

Staging and Operability

With a tumor type as lethal as pancreatic carcinoma, the practical goal of staging with imaging studies is to definitely identify patients who are not surgical candidates. At the same time, such determinations must be made with a great deal of reliability to ensure that patients with curable disease are not excluded from appropriate surgical treatment.

Of the 27,000 cases that are diagnosed each year in the United States, 75% to 90% are ductal adenocarcinoma. The untreated survival rate is 3 to 6 months, and the 5-year survival after a Whipple procedure is 18% to 20%.²⁴⁸ The numbers of patients qualifying for the different treatments vary according to the reporting institutions, but generally, 90% of patients presenting for care have locally advanced or disseminated disease; 95% succumb to disease within the first year. Only 20% to 25% of those undergoing surgical exploration have resectable disease. For this group, there is a 15% to 20% survival. These percentages provide a practical perspective on the potential for treatment of pancreatic carcinoma.

The traditional TNM classification is still the standard used by most authors. In view of the dismal response of past treatment methods, there is a tendency to avoid spe-

cific staging because it seems futile. In reality, it is important that staging approaches continue because there are very innovative diagnostic and treatment strategies in development that promise to improve the outcome of pancreatic cancer. This classification, as shown in Table 38-4, depends on location, extension, lymph node involvement, involvement of vessels, and metastases.

Surgical Strategies

Whipple Procedure. Resection of the pancreas and duodenum was first performed by Kausch in Berlin in 1912.²³⁵ The procedure was popularized in the 1940s by Whipple and colleagues. With this procedure, the pancreatic tumor of the head is resected en bloc with the duodenum. Anastomotic attachments are then made with the small bowel, biliary system, and pancreatic duct. This procedure was originally used only for ampullary cancer, but now has been extended to cases with periampullary tumor and local tumor with limited staging. Over the years, the survivorship of the procedure has not changed significantly, but the mortality and morbidity of the procedure have improved. The mortality has improved from 20% to less than 4%. Current data also indicate a difference in mortality between

Figure 38–118. A, Normal venous drainage of the pancreaticoduodenal veins. PV, portal vein; SV, splenic vein; PS, posterior-superior pancreaticoduodenal vein (PSPDV); PI, posterior-inferior pancreaticoduodenal vein (PIPDV); AS, anterior-superior pancreaticoduodenal vein (ASPDV); AI, anterior-inferior pancreaticoduodenal vein (AIPDV); GC, gastroduodenal trunk; SMV, superior mesenteric vein. Arrows indicate direction of drainage of the posterior pancreaticoduodenal venous arcade. B, Occlusion of the confluence of the portal superior mesenteric vein (P-SMV) by advanced cancer of the pancreas. The PSPDV dilates because it is one of the hepatopetal collateral veins. C, Tumor extension to the right lateral wall of the P-SMV (open arrows) with occlusion of the PIPDV. The AIPDV, ASPDV, and gastroduodenal trunk may also be occluded. The PSPDV drains blood from the posterior pancreaticoduodenal arcade and probably also from the anterior pancreaticoduodenal arcade via anastomotic branches into the portal vein. D, Occlusion of the PIPDV with no tumor invasion of the P-SMV. The ASPDV and AIPDV may or may not be occluded. The PSPDV drains blood from the posterior pancreaticoduodenal arcade and, when the AIPDV is occluded, also from the anterior arcade. (From Mori et al: Radiology 181:793–800, 1991.)

tertiary centers (2% to 4%) and low-volume hospitals (12% to 14%). The morbidity has diminished from 50% to 40%.²⁰⁸ The most common complication is anastomotic leakage.

Whipple Procedure with Pylorus Sparing. This procedure is identical to the standard Whipple, except that pylorus is preserved to permit gastric reservoir function and a more normal gastrointestinal physiology. Patients who undergo this modified procedure have shorter operative times, reduced blood loss and fewer transfusions, comparable gastric function, and comparable survival.

Regional Pancreatectomy. This procedure consists of more extensive surgery with removal of local lymph nodes and some vein resection. The lymph nodes from the diaphragm to the level of the inferior mesenteric artery are removed, including the periaortic, portal, and perirenal lymph nodes. The limited data available do not clearly

demonstrate any improvement in survival with regional pancreatectomy.

Vascular Resection. The purpose of vascular resection was to improve resection rates and rates of achievement of negative resection margins. Local involvement of venous structures is present in almost one third of cases and was the single barrier to resection in those cases. Although long-segment involvement of the portal or superior mesenteric vein is considered unresectable, isolated tumor adherence in a local site is not considered a contraindication.^{73a, 94a, 146a} Repair of the resected vein can be accomplished by an end-to-end anastomosis or a vein graft. As one might expect, the resection of veins prolongs operative time and increases blood loss and need for transfusion.

Total Pancreatectomy. The rationale behind total pancreatectomy was based on theoretical advantages of eliminating multifocal disease, achieving wider resection mar-

Table 38–4. Standard Classification of Tumors of the Pancreas

Staging			
Stage I	T1	N0	M0
	T2	N0	M0
Stage II	T3	N0	M0
Stage III	Any T	N1	M0
Stage IV	Any T	Any N	M1
Primary Tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
T1	Tumor limited to the pancreas		
	T1a Tumor 2 cm or less in greatest dimension		
	T1b Tumor more than 2 cm in greatest dimension		
T2	Tumor extends directly to the duodenum, bile duct, or peripancreatic tissues		
T3	Tumor extends directly to the stomach, spleen, colon, or adjacent large vessels		
Regional Lymph Nodes (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Regional lymph node metastasis		
Distant Metastasis (M)			
MX	Presence of distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis		

gins, avoiding tumor cell spillage, and preventing complications of pancreatic anastomotic leak. The procedure resulted, however, in significantly higher morbidity and worse overall survival.

Distal Pancreatectomy. This procedure is less commonly discussed because (1) only 25% of tumors involve the body and tail and (2) the disease is silent and more likely present in an advanced stage. Body and tail tumors are more likely to be larger and have a higher incidence of metastatic disease. If comparable staging parameters are present, the survival rates are similar to those of head tumors. Preservation of the spleen is not critical to survival. As one might expect, the incidence of infections, blood loss, and hospital stay are improved in patients in whom the spleen is preserved.²³⁵

Role of Staging by Various Modalities

Formerly, there was great controversy about the role of various modalities for imaging the pancreas. Those opinions have now converged, so there is general agreement about the use of the many techniques available.

Because ultrasonography is so ubiquitous and easily available, it has assumed the role of initial screening for the pancreas. With the new technical refinements, it is well suited to evaluate patients with upper abdominal pain in a preliminary fashion. The method is very accurate for the detection and characterization of biliary and peripancreatic disease. Dilatation of the biliary system is easily detected and assessed by ultrasonography, so the associated findings of pancreatic mass, inflammation, or calculi can be defined. When the primary problems are related to the biliary system, little additional investigation is required, because ultrasonography is so accurate for the gallbladder, the common bile duct, and the main portion of the pancreas. When a tumor is detected, however, the accurate definition of

the extent, invasion, encasement, and characterization of unusual features typically must be accomplished with CT or MRI.

Positron emission tomography (PET) nuclear studies have yet to find an accepted role in the evaluation of pancreatic carcinoma. Although PET is capable of detecting generally any malignancies, its accuracy has been less than anticipated because of false-negative results in patients with hyperglycemia and false-positive results in patients with pancreatitis.^{53a, 70a}

MRI has been widely studied and found to be very worthwhile for the characterization of some unusual pancreatic tumors, such as endocrine tumors and also cystic types of tumors. Only the very highest-technology MRI scanners appear to be capable of accurately characterizing anatomic detail sufficiently to permit accurate staging. One of the few studies to compare CT and MRI for the staging of cancer, by Nishiharu and colleagues,¹⁸⁸ reported that the thin-section, dynamic CT is more accurate with the use of a receiver operator curve (ROC) analysis for depicting local invasion into local tissues, portal veins, and peripancreatic arteries.

Even before the introduction of the new multislice scanners, the thin-slice spiral CT scans were extremely accurate as reported in the literature. With the very thin, very high-speed, isotropic scanning of the multislice scanners, the diagnostic capabilities approximate perfection.¹⁰⁷ Philosophically, the goal of radiologic imaging is to provide imaging that closely approximates the gross anatomic findings of the pathologists. With the new submillimeter imaging, radiology is ready to cross the next threshold into microscopic or molecular imaging.

In relation to the TNM classification for pancreatic cancer, certain imaging findings are quite straightforward, such as the visualization of lymph nodes and metastases. The evaluation of local extension and involvement of the vasculature, however, is very critical to selection of patients for curative versus palliative surgical procedures.

For the detection of liver metastases, CT is well suited, as discussed in the chapter on the liver. Specific study of the technique for the evaluation of liver metastases from pancreatic cancer has been performed by Furukawa and coworkers.⁷⁷ They studied the two major CT methods for enhancing the liver, arterial portography (CTAP) and intravenous contrast-enhanced CT (IVCT). The two approaches yielded equivalent diagnostic accuracy, indicating that the clinically more complicated method, CTAP, conferred no advantage.

General local invasion of the serosa, retroperitoneum, and vessels was evaluated by Tabuchi and colleagues relative to the phase of contrast enhancement, early or late.²⁴⁷ They concluded that the early phase CT (arterial) was better than the venous or late phase for revealing tumors, tumor size, and retroperitoneal invasion.

The importance of detecting involvement of arterial invasion or encasement has been appreciated for many years. Early workers studying direct angiography were the first to observe that encasement or narrowing of the arteries was a definite indicator of inoperability (see Fig. 38–117). Early authors Megibow and colleagues¹⁷⁴ and Itai and associates¹¹³ showed clearly that even with older CT devices, the detection of encasement on CT, as manifested by loss of the perivascular fat plane, was equivalent to or more accurate than standard angiography. There is therefore little question that even though the newer spiral or multislice scanners can produce aesthetically pleasing 3D images of the vasculature, the clinical significance of these methods is small.²¹⁸ Baek and associates¹⁰ evaluated axial, 2D multiplanar, and 3D vascular CT. They reported interobserver and intraobserver errors for assessing vascular involvement to be favorable for the axial scans but very poor for the reformatted images alone. Reformatted images are worthwhile when used in conjunction with the axial scans and may on occasion be useful for revealing the major anatomic variations of the vasculature, which can affect the planning of surgical procedures. A pertinent example is the demonstration of a hepatic artery originating from the superior mesenteric artery, which might facilitate the planning of a Whipple procedure.

As the resolution of scanning devices has improved, researchers have tried to further refine the subtle variations in vascular encasement. The intent of these studies was to further define these characteristics as they related to resectability in an effort to expand the group of patients selected for curative surgical resections. The thin-section scanning techniques obviously demonstrate the perivascular fat planes better than prior methods, so a number of authors have classified the degree of encasement and correlated it with the surgical findings and resections. Lu and associates¹⁵⁷ graded the degree of circumferential involvement of the artery on a scale between 0 and 4: no involvement of the fat plane was 0, 0 to 25% was grade 1, 25% to 50% was grade 2, 50% to 75% was grade 3, and more than 75% was grade 4 (Fig. 38–119). Their final conclusion was that contiguity of the tumor more than one half of the arterial circumference was highly specific for unresectability. Park and colleagues¹⁹⁷ studied patients with encasement of vessels and looked at the length and extent of involvement as well as at the number of vessels involved. The group found that relative to judgments made

at the time of surgery, a curative resection in preference to a palliative procedure was performed in patients with less than a 2-cm length of vascular involvement. Unfortunately, there were no differences in the survival between the resected and unresected groups.

The other types of vessels that must be considered when determining operability are the venous structures. The assessment of the major veins—portal, splenic, and superior mesenteric veins—can be made on either CT or MRI. Involvement of the larger veins can be determined by looking at the margin of the vessels during maximal enhancement and also at the associated formation of collaterals around the porta hepatis or the spleen. Assessment of subtle changes of the portal vein or the confluence of the portal and the superior mesenteric veins is best made with high-resolution endoscopic ultrasonography.

Involvement of the smaller peripancreatic veins provide insights about local invasion of tissues and can indicate when surgical resection is inappropriate. Yamada and associates²⁶⁷ and Vedantham and colleagues²⁵⁷ have noted the importance and consistency of visualizing normal veins as well as those in patients with cancer. Occlusion or narrowing of the veins by tumor produces flow of blood away from the tumor through established collateral channels. In patients who have invasion of the third portion of the duodenum, the inferior veins are occluded, producing dilatation of the more superior veins. When the second portion of the duodenum is invaded, the superior/anterior veins are likely to be included, so the more inferior veins are likely to be dilated.

Laparoscopy has recently been considered as an important adjunct after routine imaging studies and preceding surgical resection. Some workers at Massachusetts General Hospital advocate the use of laparoscopy. Warshaw and colleagues²⁶¹ recommend the use of laparoscopy and peritoneal cytology to improve the detection of peritoneal metastases. Others have shown that this approach excludes from surgery only 4% to 13% of patients whose tumors have been staged with optimal CT techniques.²⁰³

The simplest and most reliable factor indirectly related to favorable tumor staging is the size of lesions. Manabel and coworkers^{162a} previously reported a 4-year survival of 37% for patients with a tumor smaller than 2 cm. Similarly, Pantalone and associates¹⁹⁴ reported that patients whose tumors were completely confined to the gland had a survival of 31%.

Unrelated to the anatomic staging as discussed here is the histologic characteristics of the various tumors. Kloppel and Maillet¹³⁴ demonstrated that patients with poorly differentiated adenocarcinoma tumor have the poorest prognosis, all of their patients having died within 15 months. Similarly, Fukushima and coworkers⁷⁵ confirmed that even in patients presenting with intraductal carcinoma, who generally have a better prognosis than those with other forms of pancreatic tumors, poorly differentiated intraductal tumors have a very high mortality; there were no survivors after 3 years in their study.

Prognosis Based on Staging. One of the most complete studies of staging and prognosis was by Freeny and others,⁶⁶ who evaluated the accuracy of CT staging relative to operative findings and also looked at the overall outcome

of their patients. They studied a series of 174 patients over a 6-year period. They judged tumors as resectable if there was an isolated pancreatic mass with or without ductal dilatation or combined pancreas–bile duct dilatation without an identifiable pancreatic mass. Tumors were judged unresectable if one or more ancillary findings of carcinoma were present, including local tumor extension, contiguous organ invasion, metastases, ascites, and vascular involvement.

Although the data in the literature about the current outcome of pancreatic carcinoma are discouraging,^{32, 47, 48, 59} they clearly demonstrate that CT has a definitive role for diagnosing, staging, and predicting the outcome of surgical treatment. CT is and will be especially helpful for following the course of the disease during the development of

study of new therapeutic regimens (Fig. 38–120). Further refinement of MRI may assist in these goals.

Distinguishing Between Carcinoma and Pancreatitis. Most authors agree that it is difficult to make a distinction between carcinoma and pancreatitis on the basis of imaging studies alone.^{143, 148, 183} Carcinoma can coexist with pancreatitis, even though there is no proof that a close relationship exists. Kim and associates¹³¹ reported that the intrapancreatic fibrotic changes, as visualized on enhanced CT or MRI, cannot be distinguished from carcinoma.

Several diagnostic points are helpful in distinguishing the two diseases. The most definitive method for distinguishing them is evidence for spread of malignancy, such as liver metastases or extensive local spread. Factors that

Figure 38–119. A, CT scan of a 67-year-old woman with grade 1 vessel involvement. Pancreatic-phase thin-section CT image of pancreatic head adenocarcinoma (T) shows minimal tumor contiguity to the superior mesenteric vein (SMV) (arrow). Contiguity is less than one quarter the circumference of the vessel. At surgery, the SMV was found to be free of tumor.

B, A 59-year-old woman with resectable grade 2 vessel involvement. Pancreatic-phase thin-section CT image of pancreatic head adenocarcinoma (T) shows contiguity of the tumor to the lateral wall of the superior mesenteric vein (SMV) for up to almost one half the circumference (between arrows). At surgery, the tumor was easily freed from the SMV. Note the marked pancreatic ductal dilatation (arrowheads) and normal enhancing pancreatic parenchyma (P).

C, A 62-year-old man with unresectable grade 3 vessel involvement. Pancreatic-phase thin-section CT image of the celiac axis (C) with pancreatic head and neck adenocarcinoma is shown. Note the cuff of tumor on both sides of the hepatic artery (arrowheads); images inferior to the slice showed main tumor bulk, and the image immediately above the slice showed no tumor cranial to the hepatic artery, indicating grade 3 involvement. Hepatic artery was adherent and unresectable at surgery.

D, A 72-year-old woman with unresectable grade 4 vessel involvement. Pancreatic-phase thin-section CT image of pancreatic neck and body adenocarcinoma reveals circumferential encasement of the celiac artery (arrow) as well as the hepatic artery (arrowheads) and proximal splenic artery.

(From Lu DSK, Reber HA, Krasny RM, et al: Local staging of pancreatic cancer. Criteria for unresectability of major vessels as revealed by pancreatic-phase, thin-section helical CT. *AJR Am J Roentgenol* 168:1439–1443, 1997.)

Figure 38-120. A, Patient with adenocarcinoma, before treatment. CT scan shows an enlarged pancreatic duct (arrow) that has a duct-to-gland diameter ratio less than 0.5. B, After chemotherapy, the pancreatic duct returned to normal size.

would support pancreatitis are not as definite but may be suggestive. Pancreatitis is also more likely to produce diffuse changes in the gland and peripancreatic inflammation. The peripancreatic findings of thickened fascia occur in almost all cases of pancreatitis and only seldom in neoplasms. The appearance of the distal dilated common bile duct and the configuration of a dilated pancreatic duct may also be helpful. It is also true that loss of fat planes around arteries occurs more commonly in neoplasm, but it may be observed occasionally in pancreatitis.

In the final analysis, no imaging system is capable of absolutely differentiating carcinoma from inflammation or benign masses in the pancreatic area. Pathologic confirmation is necessary.^{90, 110} CT and ultrasonography currently provide remarkable assistance for percutaneous sampling procedures, and MRI promises to provide the same capability.

CT Combined with ERCP. Frick and associates⁶⁸ reported on patients studied by CT immediately after injection of contrast material during ERCP. The authors did not specifically alter the ERCP study to optimize the CT study in any way. They found that the normal gland demonstrated diffuse homogeneous enhancement that persisted for several minutes on CT. Areas of pancreatitis showed irregular contrast distribution, presumably resulting from duct distortion. Obliteration of the duct by neoplasms resulted in absence of "stain" on the pancreatogram and clear delineation of the mass on the CT image. This combined technique has not gained widespread support, so at this time it represents merely a historical perspective. Perhaps, however, future work with the high-resolution multislice scanners will be performed.

Squamous or Adenosquamous Carcinoma. Squamous or adenosquamous carcinoma is a rare variant with some specific differential pathologic and radiographic findings, but the outcome and prognosis are not much different from those in ordinary adenocarcinoma. In several large series, squamous or adenosquamous carcinoma occurred in less than 0.5% of all cases of carcinoma.

This carcinoma is said to occur predominantly in men. The clinical presentation and outcome are said to be no different from those in regular adenocarcinoma. The ap-

pearance is somewhat characteristic because the density of the tumor appears to be low as a result of necrosis within the mass (Figure 38-121).

Acinar Cell Tumors. Acinar cell tumors, which arise from acinar elements of the pancreas, are rare, occurring in 1% to 3% of all cases. An association with subcutaneous and intraosseous fat necrosis has occurred in only 20 cases.

Acinar cell tumors have a constellation of unique clinical signs. Symptoms are due to panniculitis or fat necrosis and consist of joint swelling, tenderness, and cutaneous nodules resembling those of erythema nodosum. Laboratory studies usually show leukocytosis, eosinophilia, and elevated lipase levels. Radiographs can show lytic areas involving medullary or cortical bone. These later changes are presumed to be due to a release of excessive amounts of lipase into the blood.

The prognosis of the disease is poor, the patient living 2 to 12 months. Most cases of the disease are not diagnosed until autopsy.

Radin and associates²⁰⁹ and Lim and Ko¹⁵³ have reported cases of acinar cell carcinoma. CT showed a well-circumscribed mass with some central necrosis (Figs. 38-122 and 38-123). The unique aspect of these cases is the presence

Figure 38-121. Large soft tissue mass in pancreas is low in density and had the appearance of a fluid mass. It proved to be a necrotic squamous cell carcinoma.

Figure 38-122. Acinar cell carcinoma. A, Transverse sonogram shows a well-demarcated solid tumor containing a necrotic area. B, CT scan obtained after injection of contrast material discloses a sharply circumscribed mass arising from the body and tail of the pancreas. The mass contains necrotic areas and a calcification. C, Splenic arteriogram shows a vascular mass with staining and vascular draping. (From Lim JH, et al: Clin Imaging 14:301-304, 1990.)

of a permeative lytic process, which may involve the phalanges of the hands and feet. A radionuclide bone scan also showed diffuse periarticular uptake around the peripheral joints.

Other Tumors. A variety of other tumors can arise in the pancreas from connective or lymphatic tissue, including lymphoma, fibrosarcoma, leiomyosarcoma, fibrous histiocytoma, pancreatoblastoma, lymphangioma, and plasmacytoma.^{76, 193, 249, 263}

Specifically, lymphomas of the pancreas have no pathognomonic features, but Merkle and associates¹⁷⁷ re-

ported several suggestive findings. They noted that adenocarcinoma of the pancreas was more likely to produce ductal dilatation than lymphoma. Lymph node involvement below the level of the renal pedicles was more characteristic of lymphoma than of adenocarcinoma.

Ductal and Parenchymal Cystadenoma and Cystadenocarcinoma. If one takes a long-term perspective on pancreatic tumors, it is apparent that the basic pathologic conditions and processes of pancreatic tumors have not changed but rather that our imaging capabilities have improved. The disease processes have not changed significantly, but our understanding of the various stages and presentation of these tumors has evolved. The basic purpose of radiologic imaging is and has been to display and portray the general anatomic appearance of disease processes. When imaging modalities were rather primitive with relatively poor resolution, the end-stage processes were typically displayed, and assumptions relative to those observations were made. Now that imaging devices have isotropic volume pixels and rapid data acquisition, and using the experience gained over the past 25 years, we can better understand the appearances of the cystic and mucinous tumors of the pancreas.

Review of current literature on cystic tumors reveals that a consensus has developed about these tumors. Authors note that intraductal mucinous tumors may develop in either the main duct or side duct, whereas the classic cystic mucinous tumor develops from ductal cells in the periphery of the gland without direct communication with the duct. Because the intraductal variety originates within the duct, symptoms invariably develop related to ductal obstruction, such as pain and pancreatitis, while the classic mass is

Figure 38-123. Acinar cell carcinoma. CT scan shows a well defined mass with a small area of necrosis. A dilated pancreatic duct is noted distally. (From Mustert B, et al: Appearance of acinar cell carcinoma of the pancreas on dual-phase CT. AJR Am J Roentgenol 171:709, 1998.)

silent and without symptoms until the mass effect causes the patient to present to a physician.

Intraductal Papillary Mucinous Neoplasms. This tumor is also called mucinous ductal ectasia, ductectatic cystadenoma or cystadenocarcinoma, mucin-hypersecreting tumor, mucinous villous adenomatosis, intraductal papillary mucinous tumor, and intraductal papillary neoplasm. Intraductal papillary mucinous tumor was originally described by Itai and colleagues,¹¹² who noted its common occurrence in the uncinate portion of the gland. Another early author, Agostini,¹ noted that the tumor typically produced a cluster of thin-walled cysts. Although the clinical experience of these unusual tumors is somewhat limited, it is clear that they have a number of distinctive features. Accurate preoperative diagnosis is important because it has been shown that surgical treatment can have excellent outcome. The differences from the classic cystic tumor occur in the clinical presentation, site of development, and imaging appearance.

The clinical presentation of the ductal tumors differs greatly from the classic traditional cystic tumors. The tumors cause ductal obstruction, so symptoms due to pancreatitis, pain, and pancreatic insufficiency may occur. The cystic tumors are usually asymptomatic and are found incidentally at physical examination or imaging.

Fukukura and associates⁷⁴ and Grogan and colleagues⁸⁴ have best described the various imaging and clinical parameters related to this tumor (Fig. 38–124). Fukukura and associates⁷⁴ noted that the most common features in their patients were a dilated main pancreatic duct and a lobulated multilocular cystic lesion in the uncinate portion of the gland (Fig. 38–125). The dilated main pancreatic duct had certain features of importance for determining malignancy as well as characterizing the nature of the papillary component. These researchers also observed that lesions that were malignant produced dilatation of the duct greater than 10 mm and that papillary projections into the ducts could be seen on thin-section CT (Fig. 38–126).

Figure 38–124. CT scan of a 68-year-old man with benign intraductal papillary mucinous tumor. A, Helical CT scan shows papilla (arrowheads) bulging into duodenal lumen (straight arrows). Note that papilla is contiguous with main pancreatic duct (curved arrow). B, Helical CT scan shows multilocular cystic lesion (arrowheads) without papillary projections in uncinate process. C, Helical CT scan obtained at level directly below that of B shows communication (straight arrow) between dilated main pancreatic duct (curved arrow) and cystic lesion (arrowhead). D, Histologic specimen shows communication (straight arrow) between main pancreatic duct (curved arrow) and cystic lesion (arrowhead) covered by papillary epithelium smaller than 1 mm. (H and E, ×1.) (From Fukukura Y, Fujiyoshi F, Sasaki M, et al: Intraductal papillary mucinous tumors of the pancreas: Thin-section helical CT findings. *AJR Am J Roentgenol* 174: 441–447, 2000.)

Figure 38-125. A 75-year-old man with a malignant intraductal papillary mucinous tumor. **A**, Helical CT scan shows dilatation of main pancreatic duct (arrow). Pancreatic parenchyma is markedly atrophic. **B**, Helical CT scan shows papillary neoplasms (arrowheads) as slightly heterogeneous soft tissue in dilated pancreatic duct. Invasive carcinoma in pancreatic parenchyma is not seen. **C**, Photograph of excised specimen corresponding to **B** and **C** shows dilated main pancreatic duct filled with 8-mm papillary neoplasms. **D**, Photomicrograph of histologic specimen corresponding to **B** and **C** shows invasive adenocarcinoma components (arrows) in pancreatic parenchyma. (H and E, $\times 5$.) (From Fukukura Y, Fujiyoshi F, Sasaki M, et al: Intraductal papillary mucinous tumors of the pancreas: Thin-section helical CT findings. *AJR Am J Roentgenol* 174:441-447, 2000.)

Grogan and colleagues⁸⁴ noted the classic appearance of the large defined tumors and the newly described appearances of the intraductal tumors. The typical ductal tumor may begin in the main duct, resulting in a focal unilocular mass, and may have the appearance of a pseudocyst (Figs. 38-127 and 38-128). Even if an aggressive surgical approach is taken, such tumors may progress, leading to death. When such tumors involve the side branches, the entire ductal system may become distended and have the appearance of grape clusters.

The prognosis of intraductal papillary mucinous tumors is quite good with appropriate surgical management. Cuillerier and associates⁵⁰ reported the outcome of a group of 45 cases treated with total or partial pancreatectomy. The 3-year survival was 83%. The authors recommend partial resection for noninvasive carcinoma, guided by frozen-section examination, until disease-free margins are obtained. Total pancreatectomy is likely to cure patients with invasive carcinoma, but potential morbidity and mortality should be considered.

Cystadenoma and Cystadenocarcinoma. Cystadenomas and cystadenocarcinomas are rare tumors thought to originate from the ductal epithelium. They are distinctly different in presentation, histologic appearance, imaging characteristics, treatment, and prognosis. Several terms have been applied to them, but they are divided into two types, one thought to be a benign type, called *microcystic cystadenoma* (serous cystadenoma or glycogen-rich cystic tumor), and a premalignant or malignant type, called *macrocytic cystadenoma* (mucinous cystadenoma). Patients with these tumors usually have a gradually increasing tumor mass. They may or may not have pain and weight loss.

Considerable attention has been focused on these two lesions and the methods to distinguish them. In 1962, Campbell and Cruickshank³⁶ observed that the two entities could be differentiated by pathologic criteria. In the benign type, they noted a relatively uniform population of cells without any evidence of malignant changes. In the malignant type, they noted a distinctly different pattern that showed malignant changes scattered throughout the tumor.

Figure 38-126. Small cystic mass (arrow) in the neck of the pancreas proved on histology to be a macrocystic tumor with mucinous components.

Although these researchers did not actually observe the transition in a patient, they postulated that malignant degeneration occurred in the latter type. Histologically, they found the benign tumor had cuboidal epithelium, with little secretion of mucus. The tumor with scattered changes of malignant tissue had tall, mucus-secreting epithelium and large, mucin-filled cystic spaces.

In 1978, Compagno and Oertel^{45, 46} clearly defined the histologic difference between what they termed *benign microcystic* (glycogen-rich or serous) *cystadenomas* and *mucinous cystic neoplasms* (cystadenocarcinoma and cystadenoma) with overt and latent malignancy. They also

noted distinct differences in the clinical data between the patients with the two distinctly different tumors.

Microcystic adenomas occur more commonly in patients 60 to 70 years old and equally in men and women. Some patients were symptomatic, with local pain or discomfort related to the mass, whereas others had no symptoms; some were tumors found incidentally at autopsy. The tumors had a mean diameter of 10.8 cm and showed small cysts with glycogen but little or no mucin. They most commonly occurred in the head of the gland. Fatalities most commonly occurred from complications of surgery or obstruction of the gastrointestinal or biliary system.

Clinical data about mucinous cystic (macrocytic) neoplasms or cystadenocarcinoma differed greatly from the microcystic tumors. Mucinous cystic neoplasms occurred in a younger group of patients, most commonly female, with mean and median ages of 49 years. The symptoms were similar to those of microcystic cystadenomas but were more diffuse and severe. Patients had epigastric pain or discomfort, with some radiation of pain to the back. They had also anorexia, weakness, and weight loss. The tumors commonly appeared in the body and tail of the pancreas. Histologically, the masses showed larger cystic areas that were lined with columnar, mucin-producing epithelium.

Imaging Appearance. Although these tumors are fairly uncommon, a considerable experience has now been reported in the literature that characterizes their imaging appearance.^{18, 69, 119, 137, 196, 215}

One of the first reports, by Friedman and coworkers,⁶⁹ detailed the radiologic and pathologic correlation in 35 cases of cystic pancreatic neoplasms. CT and ultrasonography findings paralleled closely the gross anatomic appearance of the tumors. Microcystic adenomas have a mixed variety of appearances that are similar to the gross anatomic findings. CT scan with contrast enhancement showed a mixture of connective tissue and fluid density. Ultraso-

Figure 38-127. A, CT scan shows a cystic mass in the pancreatic head (arrow), which has caused adjacent atrophy of parenchyma, although the distal portion of gland is intact. Contrast this scan with that shown in Figure 38-124. Both appearances are typical variations of intraductal mucinous tumors. B, Later scan in same patient shows that the cystic tumor has broken through the pancreas and is invading the porta hepatis region. Tumor invasion of the fat planes around the portal and arterial structures is seen. Because such mucinous tumor is not as "hard" as the sclerotic adenocarcinoma, typical encasement of the arteries is not so prevalent.

Figure 38-128. A, Intraductal papillary mucinous tumor of the midportion of the pancreas shows characteristic changes. There is severe dilatation of the pancreatic duct (D) with dilatation of the side branches (c), producing cystlike structures. In the head, the dilated duct, with small central calcification (arrow), can be seen. Dystrophic calcifications can occur in concretions of chronic mucin plugs. B, BCRP shows dilated pancreatic duct, with filling defect with small calcifications (arrow) in same patient. (A from Grogan JR, Saeian K, Taylor AJ, et al: Making sense of mucin-producing pancreatic tumors. *AJR* 176:921-929, 2001.)

nography revealed a mixed pattern; angiography showed hypervascularity. Mucinous neoplasms showed large cystic changes on CT and sonography. Both types of cystic tumors had calcifications. Other authors, including Freeny and associates⁶⁴⁻⁶⁷ and Carroll and Sample,³⁸ have reported similar findings. Itai and associates¹¹² reported that all tumors they studied appeared cystic in nature, with the major distinction being the number and size of the cystic areas. The macrocystic (mucinous) form was said to have larger and fewer cystic areas, compared with the microcystic form. Wolfman and coworkers²⁶⁶ reported several cases of the microcystic type appearing solid on the ultrasonography and CT.

Two additional studies were informative relative to the appearance of these tumors. One study, by Johnson and associates,¹¹⁹ evaluated the various imaging criteria as applied by a number of blinded readers, and a second study, by Warshaw and colleagues,²⁶¹ evaluated a large series of cystic tumors and made observations concerning the clinical, radiologic, and pathologic findings.

Johnson and associates¹¹⁹ studied 45 cystic tumors, which included 16 microcystic adenomas, 17 mucinous cystadenomas, and 12 mucinous cystadenocarcinomas. They evaluated the number of cysts, size of cysts, and presence of calcifications (Figs. 38-129 to 38-132). The authors concluded that one should be cautious in using imaging studies for making the diagnosis of microcystic or mucinous tumors because there is considerable overlap with pseudocysts and other tumors, such as ductal adenocarcinoma, papillary and solid epithelial neoplasms, and pancreatic lymphangiomas. They did observe that the typical appearances as described subsequently were present in 50% of the microcystic adenomas and about 90% of the mucinous cystadenomas and cystadenocarcinomas. Signs for the microcystic adenomas include multiple cysts smaller than 2 cm; the macrocystic adenomas were larger than 2 cm. Calcifications were present in both tumors.

Warshaw and colleagues²⁶¹ commented about the calcifications and noted that the calcifications were not specific. Only 2 of the 18 patients with microcystic adenomas showed the typical starburst configuration.

The latest study, by Fugazzola and coworkers,⁷³ reconfirmed the findings of earlier researchers on more current scanners. They noted that 7 of 11 tumors became partly or diffusely hyperdense after intravenous contrast administration compared with normal pancreatic tissue. One of their patients had a multiseptated mass with calcified walls. Calcifications were visible in three other cases. Metastases from these tumors may or may not parallel the findings of calcifications and increased vascularity.

In my experience, the described findings apply in most cases, but several points should be clarified. These tumors are vascular with good contrast enhancement. When the

Figure 38-129. Large microcystic tumors of the pancreas may demonstrate considerable enhancement, as shown here. Note that the cystic changes are so small that definition of small cystic spaces is difficult.

Figure 38-130. Microcystic adenoma. *A*, Plain CT scan. Large, lobulated cystic mass with foci of central calcifications. *B*, Selective angiography. Enlarged pancreatic feeding arteries from the gastroduodenal artery. (From Mathieu D, Guigui B, Valette PJ, et al: Pancreatic cystic neoplasms. *Radiol Clin North Am* 27:163-176, 1989.)

Figure 38-131. *A*, Macrocystic adenoma (arrowhead). Low-density mass in the head of the pancreas was appropriately resected. *B*, Dynamic scan of the same mass shows enhancement of the cystic tumor.

Figure 38-132. More typical macrocystic tumor (M) shows a large mass in the body of the pancreas, in front of the splenic vein.

tumor is small overall, it is difficult to characterize the cysts within it. Furthermore, I am convinced that imaging appearance (CT or other) is not sufficiently characteristic to differentiate the two tumor types, as some authors imply. Using the imaging traits previously listed, I saw two cases that progressed contrary to what I would have predicted. These two cases should have been classified as microcystic on the basis of the imaging appearance, yet both patients over the course of several years had growth of the tumor and subsequently died from carcinoma (Fig. 38-133). Several authors have reported on the benefits of percutaneous procedures for diagnosing the presence of cystadenocarcinoma, but even they recommend removal of the tumors regardless of the outcome of the cytologic study.⁷³ I believe that all tumors should be surgically removed until definitive data appear indicating that a preoperative differentiation can be made by imaging or biopsy (see Chapter 61).

Papillary Neoplasms. Papillary neoplasms (solid and papillary epithelial carcinoma, papillary carcinoma, papillary-cystic carcinoma) are unique because their surgical resection is associated with a good prognosis.^{41, 70, 200} The diagnosis, however, can be difficult to make preoperatively. In one case, the patient was healthy at the end of several years, and the original diagnosis, cystadenocarcinoma, was

Figure 38-133. A, Completely asymptomatic tumor with small cysts (arrows) measuring less than 2 cm; the tumor should be microcystic according to the criteria in the literature. The patient refused surgery. B, The patient had widespread pancreatic carcinoma 6 months later (autopsy proven).

changed retrospectively to papillary carcinoma (Fig. 38-134).

Demographically and histologically, papillary neoplasms vary significantly from other tumors. They usually occur in women around 26 years of age. The symptoms are related to vague abdominal symptoms, in turn related to the large size of the tumor; papillary neoplasms have even been found incidentally during surgery for other problems.

Pathologically, these tumors lack the microacinar patterns common to islet cell tumors and contain papillae as well as cysts of different sizes. The numerous small cysts and myxoid stroma may suggest microcystic adenomas, but they lack the glycogen. The nature of these tumors is not aggressive, and they seldom metastasize; surgical removal may produce good chances for survival.

The first report of CT findings was by Balthazar and associates¹⁴ in 1984. The characteristic CT findings were described as somewhat specific. These researchers de-

scribed the papillary neoplasm as a sharply defined nonhomogeneous mass of uneven soft tissue density undergoing central necrosis. Contrast infusion produces no central enhancement and only slight peripheral enhancement. Although ill-defined cystic components should be expected, a sharply outlined, septate appearance, central scarring, or calcification would be unusual. Ultrasonography in their study showed a diffuse echogenic mass with no through transmission. Angiographically, the vessels should be displaced and stretched but not encased.

Kim and coworkers¹³⁰ reported a similar appearance on CT, but the ultrasonographic findings differ from those reported by Balthazar and associates¹⁴: a sonolucent rather than an echogenic mass.

Friedman and associates⁷⁰ reported on nine cases from the Armed Forces Institute of Pathology, which provided imaging information on seven. The tumors were large, averaging 11.5 cm. CT showed mixed cystic-solid appearance in seven cases, and two tumors were chiefly cystic, with thick walls. In one patient, there was enhancement of the edge with contrast enhancement on CT. The exact appearance on ultrasonography was not specifically noted, the authors saying only that the findings paralleled the histologic information. Choi and coworkers⁴¹ reported six additional cases and confirmed similar findings on CT.

Figure 38-134. Papillary epithelial tumor. The patient has a large mass with cystic areas and a well-encapsulated margin. The true nature of this lesion was not shown until the patient survived many years and a review of the pathologic sections was made. Diagnosis was changed from cystadenocarcinoma to papillary epithelial tumor. (Courtesy of Dr. D.H. Stephens, Rochester, MN.)

Endocrine Tumors

Islet Cell Tumors. Islet cell tumors differ from neoplasms of the acinar portion of the gland because they originate in the various cell lines of the islets of Langerhans.⁴⁹ The cell types and their corresponding products according to the Lausanne classification are A cell, glucagon; B cell, insulin; D cell, somatostatin; D1 cell, vasoactive intestinal polypeptide; EC cell, 5-hydroxytryptamine; G cell, gastrin; P cell, bombesin; and PP cell, pancreatic polypeptide.⁸¹

Depending on the tumor's degree of function, signs and symptoms may or may not be associated with endocrine secretion. Tumors reported to cause syndromes include glucagonoma, insulinoma, gastrinoma, vipoma (watery diarrhea, hypokalemia, and anacidity), and somato-

statinoma.^{81, 212} There have been reports relating to CT evaluation of these rare entities.

In addition to being isolated, these endocrine tumors can also be associated with the multiple endocrine neoplasia syndrome, specifically type I (Wermer's syndrome). Type I includes pituitary, pancreas, and parathyroid tumors; type II (Sipple's syndrome) includes thyroid, adrenal medulla, and parathyroid tumors; and type III includes thyroid, adrenal medulla, mucosal nerve, and ganglion cell tumors.^{81, 255}

Nonfunctioning Islet Cell Tumors. There may be both benign and malignant islet cell tumors that do not function. Benign tumors are seldom seen because they do not produce hormones and do not grow large enough to appear as abdominal masses. The patient with malignant tumors usually has vague abdominal symptoms produced by the large size of the tumor mass.²⁵⁵ It is important to differentiate these malignant tumors from the typical adenocarcinoma of acinar origin, because the prognosis and treatment vary considerably. In these tumors, special stains may demonstrate endocrine products; a clinical syndrome from excessive products may not be present.

As reported by Eelkema and associates,⁵⁵ the typical CT appearance of this mass includes three specific findings: The tumors are typically large, contain calcification, and show increased enhancement with dynamic bolus arterial studies (Figs. 38–135 and 38–136). Slight differences among the various series were noted in the size and homogeneity of the mass. Stark and colleagues^{242, 243} noted calcification in only one of five cases. Eelkema and associates,⁵⁵ in a report about 27 patients, noted that the soft tissue mass could have a variable density (i.e., either homogeneous or heterogeneous); when comparison was possible, most of these tumors were isodense with the normal gland, and only a few were more or less dense than the normal gland. Finally, nonfunctioning islet cell tumors grow slowly, and they show minimal change over long periods, even years. In most cases, oncologists delay treatment until symptoms are present regardless of imaging appearance.

General Localization of Functioning Islet Cell Tumors. Although absolute localization of the endocrine-producing tumors depends on imaging methods as described subsequently, Howard and coworkers¹⁰⁵ have de-

scribed a general localization of the various tumors. Studying their data on endocrine tumors, they found a bimodal distribution of the various tumors. In cluster 1, which included gastrinomas, pancreatic polypeptide-secreting tumors, and somatostatinomas, the tumors occurred in 75% of cases to the right of the superior mesenteric artery. In cluster 2, which included insulinomas and glucagonomas, 75% of the tumors occurred to the right of the superior mesenteric artery. These researchers further noted that the distribution paralleled the expected density of the various islet cell precursors in the gland. They finally speculated that the distribution might be a consequence of embryologic development, with cluster 1 tumors originating from the ventral bud, and cluster 2 tumors originating from the dorsal bud.

Insulinoma. When a tumor of the B cells develops, the patient usually has hypoglycemia and high serum insulin levels. Whipple's triad, a set of clinical features that should suggest the diagnosis, consists of the following findings: (1) spontaneous hypoglycemia, followed by central nervous system and vasomotor symptoms, (2) blood glucose values consistently less than 50 mg/mL, and (3) relief of symptoms by administration of glucose.

These insulin-secreting tumors are generally small and usually less than 2.0 cm in diameter.⁴⁹ In 90% of cases, they are solitary and benign, being malignant in only 10% of cases. They are multiple in 8% of cases and may present as a diffuse hyperplasia or microadenomatosis in 2% of cases. Most reports show a predilection for the head of the gland.

Because insulin produces such profound hormonal symptoms, the abnormality is usually diagnosed from clinical signs and serum hormonal assays. The role of imaging is not to diagnose the problem but rather to determine the number, location, and size of the abnormality. A variety of diagnostic methods have been used, including angiography, ultrasonography, CT, percutaneous venous sampling for hormone, and intraoperative sampling of glucose correlated with palpation. The vascular sampling techniques are usually used as a method of last resort if the other methods have failed, so are not discussed here (references are provided for additional information).

Angiography was an accurate method for detecting these

Figure 38–135. A, Nonfunctioning islet cell tumor (T) shows necrotic areas and calcifications. B, Angiogram demonstrates greater enhancement during celiac arteriogram.

Figure 38-136. A, Multislice CT scan of pancreatic head shows increased vascularity of mass, consistent with non-functional islet cell tumor. B, Reconstructed angiogram shows enhancing mass (*m*) to the right of the superior mesenteric artery (*arrow*). C, Standard angiogram shows enhancing nonfunctioning islet cell tumor in the head of the pancreas (*arrow*).

tumors¹⁹² before the refinement of CT and ultrasonography. Insulinomas are well suited for this method because the tumors demonstrate hypervascularity that is clearly visualized during angiographic study. Historically, angiography has been accepted as the most accurate method, with accuracy varying between 29% and 91%, but authors such as Rossi and associates^{213, 214} have shown that angiography and high-quality CT scanning are essentially equivalent for the detection of insulinoma. Most authors suggest that because of the invasive nature of angiography, this study should be deferred until other diagnostic methods have been used. A combination of CT and angiography was reported by Krudy and colleagues¹⁴¹ and Ahlstrom and coworkers,² but this method has not gained acceptance⁶¹ because state-of-the-art scanners combined with dynamic contrast injection by mechanical injectors produce almost equivalent images.

CT scanning combined with high-dose intravenous contrast material administration by mechanical injection has been demonstrated as quite accurate for the detection of insulinomas. Numerous authors have confirmed the merits of CT for detecting this abnormality. Because these lesions tend to be small but hypervascular, the essential elements of an accurate examination include intense intravenous contrast enhancement and high-resolution scanning. Char-

acteristically, the lesions are isodense with the normal un-enhanced gland but show intense enhancement with contrast material, which may be uniform or target-like. The likelihood of detection also depends on size; tumors larger than 2 cm are detected between 90% and 100% of the time, and tumors less than 1 cm are detected with an accuracy of 45% to 50%.

Unusual findings may include small calcifications, low density,²³² or a cystic appearance. Pogany and coworkers²⁰⁶ reported an unusual cystic insulinoma.

Ultrasonography. Before the development of high-quality real-time ultrasonography, detection of insulinomas by ultrasonography was unreliable. Using real-time ultrasonography, many groups have reported favorable results for detecting insulinomas preoperatively.^{39, 44, 78, 80, 82, 86, 87, 211, 231} Using meticulous technique to ensure visualization of all parts of the gland, Charboneau and colleagues reported accuracies of 60% and 63%. Most insulinomas are sonolucent in appearance, but occasionally they are echogenic or isoechoic. When they are isoechoic, one can detect them by observing the presence of a sonolucent "halo" (Fig. 38-137).

Although the transabdominal method⁴⁵ is comparable to the detection rate as reported by CT, there is no question

Figure 38-137. A, CT scan with intense contrast enhancement shows considerable enhancement of small pancreatic insulinoma. B, Intraoperative ultrasound scan shows small echogenic mass with hypoechoic "halo" (arrowhead). This procedure still has the highest detection rate, but MRI can provide accurate preoperative diagnosis.

that the experience with intraoperative ultrasonography shows superiority of that method. The accuracy for intraoperative ultrasonography varies between 86% and 100% and has been confirmed by numerous authors.^{2, 80, 86, 87, 190} Although little data are available, a study by Thoeni and colleagues²⁵⁴ indicates that MRI with appropriately selected pulsing sequences will become the diagnostic modality of the future (see Figs. 38-34 and 38-35). These authors, in a cohort of 28 patients, showed a specificity and positive predictive accuracy of 100%. As a preoperative method, MRI appears to be the modality of choice, because intraoperative ultrasonography will be used for final localization and surgical planning.

It is my opinion that diagnostic aspiration serves no purpose in patients with suspected endocrine tumors. The probability for a catastrophic event is high, and I believe that aspiration is not in the best interest of the patient. There has been one case report about percutaneous fine-needle aspiration performed on a patient with unsuspected insulinoma, and no problems were encountered (the lesion was "cystic"). Experience with other endocrine tumors, such as the adrenal gland, has resulted in some deaths.

Gastrinoma. Gastrinomas originate in the cells of the pancreas and are associated with a specific syndrome, known as the Zollinger-Ellison syndrome. This syndrome is associated with hypersecretion of stomach acid and associated multiple peptic ulcerations refractory to traditional treatment methods; removal of the tumor, which is the source of gastrin, is the most effective treatment.

The appearance reported in the literature is as follows: The masses are of soft tissue density and may have a heterogeneous appearance because of necrosis. The lesions are vascular with dynamic bolus scanning or arterial enhancement (Fig. 38-138). Two of nine patients in one series had calcifications.

Krudy and associates¹⁴¹ reported on nine gastrinomas that were evaluated by CT, dynamic CT, angiography, venous sampling, and ultrasonography. The gastrinoma was in the pancreas in only one case; this was a 1-cm lesion in the uncinate process. In the other eight cases, the gastrinoma was in lymph nodes adjacent to the pancreas or

represented a recurrence. In five cases, the lesions were near the gland. Angiography detected six of the nine cases, routine CT detected five of the nine lesions, and dynamic CT detected two additional gastrinomas. Two lesions in small lymph nodes next to the gland were not seen by any method. Routine ultrasonography detected two of the nine lesions. Percutaneous portal vein sampling was performed in three cases and was helpful in two.

Krudy and associates¹⁴¹ found that all the lesions shown on dynamic scanning were demonstrated by angiography before CT (except one in the psoas muscle). Angiography was used to identify the location for the dynamic scan. Although the lesions probably could have been detected without CT, the surgeons found CT helpful in guiding the exploration. The limitation of the CT dynamic scan is that a large amount of contrast material must be used for sequential bolus injection; it is not practical to use CT in a primary study because of the number of boluses that would be required (see Fig. 38-138).

Stark and colleagues^{242, 243} reported a series of nine cases of gastrinoma. They found CT to be accurate for the detection and staging of gastrinomas. CT was accurate for showing the extent of the disease; in their series, four of nine tumors were curable by surgery. Angiography detected only lesions larger than 2 cm, whereas CT detected 6 of 12 lesions smaller than 2 cm.

A report by London and coworkers¹⁵⁵ defines the roles of CT, ultrasonography, and angiography for detecting and staging gastrinomas. They found that ultrasonography and CT were almost equal for the detection of hepatic gastrinomas but that CT was slightly better for extrahepatic lesions. Angiography was superior to both methods for both of these areas.

Reports by Tham and associates^{250, 251} discussed the merits of CT and MRI for detection of gastrinomas. They found no clear advantage of MRI over CT but also noted that MRI showed promise for future improvement. Because MRI showed increased intensity on T2-weighted images, these researchers speculated that with future refinements related to motion compensation and imaging time, MRI might prove to be the modality of choice for the future

Figure 38-138. Elevated gastrin levels in a 65-year-old man. *A*, Celiac arteriogram. A vascular mass (*arrow*) is near the origin of the superior mesenteric artery. *B*, Noncontrast CT scan. A gastrinoma (*arrow*) is indistinguishable from nonopacified bowel. *C*, Dynamic CT scan with intravenous bolus of contrast material shows a brightly enhancing gastrinoma (*arrow*) behind the third part of the duodenum. At surgery, an extrapancreatic gastrinoma was found in the lymph node near Treitz's ligament.

(there were no consistent signal characteristics on T1-weighted images).

If one considers the available data, it is clear that both CT and angiography are needed for the preoperative evaluation of gastrinoma. If these methods are unsuccessful in detecting a pancreatic lesion, intraoperative ultrasonography will undoubtedly be useful for detection of small lesions.

The study by Thoeni and colleagues²⁵⁴ indicates that MRI in its current, refined form will become the modality of choice for preoperative diagnosis of gastrinoma. These workers were quite successful in accurately showing gastrinomas smaller than 2 cm that were confined to the gland. Although the number of cases diagnosed by MRI is limited, it is clear that it will be the modality of choice. As with insulinomas, surgeons will continue to use intraoperative ultrasonography for final confirmation prior to resection.

Glucagonoma. Tumors of the A islet cells result in a clinical syndrome consisting of a rash, diabetes mellitus, and weight loss. When benign, the lesion may be surgically extirpated, but when malignant, it responds favorably to chemotherapeutic agents.

The largest experience reported to date has been by Breatnach and coworkers,³⁰ who reported on seven patients. Six cases showed histologic proof of glucagonoma, and one case clinical proof. Five of the six cases with histologic proof were malignant.

The masses varied from 2.5 to 6 cm in size. Densities of the masses were less than those of the normal gland after the administration of intravenous contrast material. In most cases, the tumors had clearly defined margins (in contrast to the infiltration of the planes that occurs with adenocarcinoma). Calcifications occurred in three of the six cases. The authors did not comment on the use of dynamic bolus scanning in these patients. All six patients underwent angiography, which demonstrated hypervascular lesions in all cases. Venous samplings were not mentioned.

Somatostatinoma. Somatostatinoma is the rarest of all islet cell tumors. Only eight cases have been reported, and only one case with CT findings. Somatostatinoma produces a hormone, somatostatin, that has some effect on insulin and glucagon that may account for diabetes. It is a direct antagonist of cholecystokinin, which inhibits gallbladder contractility. The clinical findings associated with this en-

tity are not as clearly defined as with other entities, but patients with this disorder have shown glucose intolerance and cholecystitis. Half have had diarrhea and weight loss.

The tumor size in the case reported with CT findings²¹² and in the other cases was quite large, 3 to 10 cm. CT findings were nonspecific and showed only a soft tissue mass. No mention of vascularity or calcifications was made. It was the author's belief that CT should be capable of detecting such lesions because of their large size.

Vipoma. Since the previous edition of this book, there has been a single report on CT and MRI imaging of a vipoma by Tham and associates.^{250, 251} They noted the tumor on CT was large, measuring 5 × 7 cm, and showed heterogeneous density with contrast enhancement. On MRI study, the tumor was isointense with T1-weighted images and hyperintense with T2-weighted images. There were no distinguishing features that would permit a preoperative diagnosis without the clinical information.

Percutaneous Biopsy. I believe that percutaneous procedures are not prudent in patients who have endocrine-secreting tumors. It is not inconceivable that a surge of endocrine products that might threaten the patient or cause a bad result could be released. An aspiration was performed without difficulty in one patient with a cystic insulinoma. The authors were not aware of the diagnosis before the procedure.

Small Bowel and Metastatic Tumors. Small bowel tumors are fairly common in the region of the third and fourth portions of the duodenum (see Fig. 38-113). In such cases, careful attention to detail is necessary to ensure proper diagnosis. Careful study of the normal anatomy around the uncinate process and Treitz's ligament enables identification of tumors in this region because of the effacement of the contrast material.

Metastatic tumors in the pancreas are not uncommon.^{182, 216} The cell types that may occur include breast, lung (Fig. 38-139), colon (Fig. 38-140), gastric, renal, pulmonary, ovarian, and gallbladder tumors as well

Figure 38-139. Axial CT scan shows low-density mass posterior to the head of the pancreas (arrow) from metastatic breast tumor.

Figure 38-140. Calcified mass (arrow), behind the head of the pancreas, secondary to colon metastasis.

as hepatoma, melanoma, lymphoma, angiosarcoma, and leiomyosarcoma. The most frequent are lung and breast tumors and lymphoma. Gastric, colon, or renal cells can contiguously spread through the adjacent ligaments. They have no distinguishing features except, at times, extension of the tumor margins from the stomach, colon, or kidney.

Postoperative Evaluation

Two types of postoperative evaluation should be discussed—one for changes associated with displacement of the gland after surgery on adjacent organs and the other for changes associated with surgery on the gland itself. In most patients who undergo resection of the kidneys or the spleen, the pancreas changes location slightly, moving toward the area where the adjacent organ has been removed. Once movement has occurred, the position remains stable, and one must then simply monitor the appearance on any subsequent examinations.

After pancreatectomy, several findings can be seen, depending on the location and type of resection. Because some type of gastric bypass will have been performed, the appearance of the surgical anastomosis of the bowel must be monitored (Fig. 38-141). If the bowel is excessively motile, administration of glucagon may be needed to immobilize it, as suggested by Heiken and associates.⁹⁷

Overall Diagnostic Accuracy

With the continued refinement of CT imaging and contrast enhancement techniques, CT scanning has continued to be the mainstay for diagnosis of pancreatic disease. In the early years of CT, considerable work was performed to compare its diagnostic accuracy with that of ultrasonography. These classic articles showed the superiority of CT.^{9, 16, 124, 181}

The largest and most comprehensive study about the pancreas evaluated the diagnostic accuracy of ultrasonography and CT.¹⁰³ In this series, which included 279 patients

Figure 38-141. CT scan of postoperative pancreas shows dilute barium in bowel adjacent to the pancreas (arrow).

(146 normal and 133 abnormal pancreases), the accuracy rate was evaluated using receiver operator curves (ROCs). Hessel and colleagues¹⁰³ found that CT was more accurate than ultrasonography for determination of normal tissue, inflammation, or neoplasm. When 44 suboptimal ultrasonographic studies were excluded, CT proved to be better. In detecting a lesion as abnormal and identifying it as malignant or inflammatory, CT had a sensitivity level of 0.84 and ultrasonography a level of 0.56.

For the evaluation of inflammatory processes, CT is superior to all other modalities. It is capable of determining the full extent of inflammatory processes and the presence of complications and can indicate the need for surgical débridement when pancreatic necrosis occurs. Furthermore, with the refinement of interventional techniques, CT offers a superior guidance method for diagnosing and treating pseudocysts and inflammatory processes.

Despite the fact that CT, ultrasonography, and MRI have improved visualization of tumors, a positive effect on the outcome of pancreatic tumors has not been seen. The mortality rate and detection rate of resectable cases have not significantly changed. It does appear, however, that diagnoses are being made earlier, with fewer studies and greater ease for the patient.

In 1983, Savarino and associates²²¹ reviewed the outcome of two groups of tumor patients, one evaluated before and the other after the development of angiography, ultrasonography, and CT. Accuracy rates for resectable tumors were as follows for the different modalities: angiography, 85%; ERCP, 88%; ultrasonography, 73%; and CT, 81%. The sensitivity levels for unresectable tumors were as follows: angiography, 88%; ERCP, 90%; ultrasonography, 75%; and CT, 85%. There was no difference in the number of resections after the development of the newer imaging tests, but the number of exploratory laparotomies was reduced.

In a review of the outcome and staging of pancreatic neoplasms by Freeny and colleagues,⁶⁶ there was a high accuracy for detection and staging of tumors, but the outcome of the patients was uniformly poor (see earlier section on tumor staging and prognosis). It seems that for the foreseeable future, the role of imaging will be to prove inoperability of tumors to prevent needless morbidity, mortality, and expense for treating incurable patients.

Cost Efficacy

CT has decreased the role of other diagnostic tests. This, of course, translates into monetary and emotional economy for the patient and the health care system. Freeny and colleagues⁶⁶ looked at two groups of patients, one group of 278 studied before CT and the other group of 300 studied after. CT enabled the correct diagnosis without the aid of other studies in 74% of the cases. Additional studies required in the other cases are as follows: ERCP, 15%; angiography, 5%; and ERCP and angiography, 5%. The accumulative diagnostic accuracy rate, for normal tissue, pancreatitis, and neoplasm, was 99% for the pre-CT group and 97% for the post-CT group. For the post-CT group, CT reduced the use of ERCP by 68% and of angiography by 54%; there was also an overall reduction in cost of radiologic diagnosis by 47%. This was an absolute dollar-value change from \$863 per case to \$459.

Fine-needle biopsy combined with CT scanning has been described by Mitty and associates.¹³⁰ They evaluated the total cost for initial diagnosis and palliation of pancreatic carcinoma in patients in whom radiologic biopsy and drainage procedures were performed. They then compared it with the cost of standard surgical methods. For 53 patients, there was an overall cost savings of \$169,800, mostly from avoidance of laparotomy and reduced hospitalization.

The Spleen

Dean A. Nakamoto, Raymond P. Onders

The spleen can be evaluated well with current cross-sectional imaging modalities. The primary imaging technique is computed tomography (CT), although magnetic resonance imaging (MRI) continues to improve. Ultrasonography is also frequently utilized, although it has limitations because of the subcostal location of the spleen and adjacent bowel gas. The advantages of CT are that it is readily available and that it allows concurrent evaluation of the other abdominal and pelvic organs.

Techniques of Examination

Current CT imaging utilizes helical scanning during a single breath-hold and intravenous (IV) administration of a contrast agent. Typically, 400 mL of dilute water-soluble oral contrast (2% to 5%) is given 30 to 40 minutes prior to the study. A mechanical injector and an angiocatheter at least 20 gauge, 100-mL bolus of nonionic contrast agent (Optiray 240 [ioversol 51%]) is administered at a rate of 2 to 3 mL/sec. Scanning is performed 45 seconds after the bolus is given. This approach typically provides uniform enhancement of the spleen and enhancement of the liver during the portal venous phase. Routine images are acquired at 8-mm intervals with a pitch of 1:1 to 1:1.5. Occasionally, thin-section images can be obtained at 4- to 5-mm intervals. For any patient being evaluated for trauma, delayed scans taken 2 to 3 minutes after the bolus often help exclude lacerations of the spleen or other organs.

MRI Protocol

Because of continuing advances in MR technology, we are always refining our MRI protocols. Our current protocol for imaging the spleen, which we also use to image the liver, is as follows. After acquiring multiplanar gradient echo localizing images, we perform following breath-hold sequences:

1. Coronal multi-slice two-dimensional (2D) HASTE (half-Fourier acquisition single-shot turbo spin-echo) sequence (TR = 4.4 msec, TE = 90 msec, NEX = 1, flip angle (FA) = 130 degrees, ST = 6 mm, matrix = 176×256 , TA = 22 sec).
2. Axial multi-slice, turbo spin-echo, T2-weighted sequence (TR = 5130 msec, TE = 138 msec, NEX = 1, FA = 180 degrees, ST = 6 mm, matrix = 116×256 , TA = 26 sec) with and without fat saturation.
3. Axial multi-slice 2D, in- and out-of-phase, T1-weighted

gradient echo sequence (TR = 144 msec, TE = 2.7 msec [in-phase] and 5.3 msec [out-of-phase], NEX = 1, FA = 70 degrees, ST = 6 mm, matrix = 119×256).

4. Axial contrast-enhanced, fat-saturated (with use of a chemical shift technique), multi-slice 2D FLASH (fast low-angle shot) sequence (TR = 152 msec, TE = 4.1 msec, NEX = 1, FA = 80 degrees, ST = 6 mm, matrix = 117×256 , TA = 17 sec), obtained after IV administration of gadopentetate dimeglumine (Magnevist; Berlex), 0.2 mL per kg of body weight. Delay times are 20 seconds, 70 seconds, 3 minutes, and 5 minutes after the start of the contrast injection.

The goal of this protocol is to image the organ as quickly as possible; examination time is about 25 minutes. The dynamic post-gadolinium images are usually the most important images. It is often helpful to employ a T2-weighted sequence with a long TE to aid in the evaluation of potential hemangiomas.

Normal Anatomy and Variants

Normal Spleen

The spleen normally lies within the left upper quadrant. The typical size of the adult spleen is $12 \times 7 \times 4$ cm, and it weighs 100 to 200 g.⁴⁶ The maximum craniocaudal length is 12 to 15 cm. The spleen is a network of white and red pulp. The white pulp consists of lymphocytes, plasma cells, and macrophages. The red pulp contains splenic cords, splenic sinuses, terminal branches of the central arteries, and pulp veins. The visceral surface of the spleen is adjacent to the stomach, left kidney, splenic flexure of the colon, and tail of the pancreas. The normal spleen may have rib notching, which should not be confused with lacerations in patients who have experienced trauma.

The spleen is usually a completely peritonealized organ. The splenorenal ligament, which connects the splenic hilum to the left kidney, contains the tail of the pancreas and the splenic artery and vein. The gastrosplenic ligament is formed by the union of the peritoneum of the lesser and greater sacs and connects the splenic hilum to the stomach. The phrenicocolic ligament connects the lower pole of the spleen to the splenic flexure of the colon and the diaphragm.

On nonenhanced CT scanning, the normal splenic parenchyma is homogeneous; it measures 40 to 60 Hounsfield units (HU), usually 5 to 10 HU less than normal liver. On T1-weighted MR images, the normal spleen has a signal

intensity equal to or less than that of normal liver, whereas on T2-weighted images, the spleen has high signal intensity. After IV contrast enhancement, the spleen can have a heterogeneous appearance on the early arterial phase images on both CT and MRI. This appearance is believed to be due to the differential enhancement of red and white pulp (Fig. 39-1). Typically, this differential enhancement can give an arciform appearance to the spleen. Occasionally, however, the enhancement pattern can simulate a mass lesion, producing a pseudomass appearance in the spleen. It is therefore important to obtain delayed images (see Fig. 39-1).

Normal Variants

Splenic clefts are common. They can usually be easily recognized because of their sharp, smooth borders. They are typically located superiorly and medially in the spleen but may occur anywhere. In patients with trauma, one should avoid misinterpreting a congenital cleft as a splenic laceration. Splenic clefts are not associated with perisplenic edema (Fig. 39-2A).

A retrorenal spleen occurs when the posterior border of the spleen lies posterior to the posterior border of the left kidney. In one series, this finding was described in 15% to

Figure 39-1. Normal splenic enhancement. Early arterial phase images may demonstrate a variety of patterns. Typically, there is an arciform appearance. Masses may be simulated, producing a pseudomass appearance, particularly during the MRI immediate after intravenous administration of the bolus of contrast agent. Therefore, delayed images are important. All of these patterns become homogeneous on delayed images. A, Normal early post-contrast, arterial phase CT scans, arciform. B, Peripheral pattern of enhancement on CT scan. C, Arciform pattern on T1-weighted, gadolinium-enhanced MR image, arterial phase. D, Hypointense splenic pseudomass on a T1-weighted gadolinium-enhanced MR image, arterial phase. E, Hypointense splenic pseudomass on a T1-weighted, gadolinium-enhanced MR image, arterial phase. Also note the rim-enhancing liver metastases.

Figure 39-2. Normal splenic variants. A, CT scan showing splenic cleft (arrow). B, CT scan showing retrorenal spleen (arrows). Note how the splenic location would make a left renal biopsy difficult.

20% of patients.⁶² It is more common in elderly patients (Fig. 39-2B).

Accessory spleens are common. They are typically located near the splenic hilum, but they can be found anywhere in the peritoneal cavity (Fig. 39-3). Accessory spleens may hypertrophy after surgical removal of primary spleen.

Congenital Variants

Congenital variations in the spleen are described in Chapter 55.

Lymphoma and Splenic Neoplasms

Lymphoma

Splenic lymphoma, probably the most common splenic malignancy, is usually seen as a manifestation of generalized (secondary) lymphoma.^{93, 114} Primary splenic lymphoma is rare, representing 1% to 2.6% of all lymphomas; most of the primary splenic lymphomas are non-Hodgkin's lymphomas.^{1, 31} The definition of primary splenic lymphoma is controversial.^{1, 43}

In general, a history of normal bone marrow findings, clinical detection of peripheral adenopathy, or both, combined with imaging data and surgical findings were used to exclude generalized lymphoma.^{1, 31} Most of the primary splenic lymphomas are non-Hodgkin's lymphoma.^{1, 31} Because primary lymphoma is rare, this discussion focuses on the features of generalized lymphoma.

The imaging appearance of lymphoma of the spleen depends on its pathologic appearance, which consists of (1) homogeneous enlargement without a discrete mass, (2) a solitary mass, (3) multifocal lesions, and (4) diffuse infiltration. Splenomegaly is the most common imaging finding, but it may be absent in up to one third of patients with lymphoma (Fig. 39-4).^{46, 117, 125} Conversely, in 30% of the enlarged spleens found in patients with lymphoma, the enlargement is benign in origin.^{43, 46, 132} Focal lesions are more common in non-Hodgkin's lymphoma than in Hodgkin's lymphoma.

Although imaging plays an important role in the detection of abnormalities in patients with lymphoma, staging of lymphomas with imaging can be limited. Forty-five percent to 70% of splenic lymphoma lesions may manifest

Figure 39-3. CT scans showing accessory spleens in unusual locations. A, Accessory spleen (arrow) lateral to the spleen's lower pole. B, Accessory spleens (arrows) inferior and lateral to the spleen's lower pole.

Figure 39-4. CT scans of splenic lymphoma. *A*, Spleen of a patient with non-Hodgkin's lymphoma and diffuse splenic enlargement with no focal splenic lesions. *B*, Spleen of a patient with non-Hodgkin's lymphoma reveals a focal low-attenuation splenic lesion (arrow). There are focal low-attenuation lesions in the liver as well (arrowheads). *C*, Multifocal low-attenuation splenic lesions in a patient with non-Hodgkin's lymphoma. *D*, Diffuse low-attenuation splenic infiltration can be seen in this patient with non-Hodgkin's lymphoma. Retroperitoneal and peripancreatic adenopathy is present as well.

as diffuse infiltration or tumor foci smaller than 1 cm.^{93, 132} Occasionally, tumor foci can be seen only microscopically; on gross visual inspection, the spleen may appear normal. Such small lesions may be difficult or impossible to visualize even with state-of-the-art CT and MRI modalities. This difficulty makes staging of lymphoma difficult. However, in patients with known disease, imaging can be used to upgrade staging—that is, to detect new retroperitoneal or mediastinal lymph nodes.

CT is the primary tool for diagnosing lymphoma and monitoring the response to therapy.^{43, 93} Helical CT scanning with IV contrast enhancement may improve the detection of smaller lesions.¹²⁵ Typically, lymphoma lesions do not enhance with contrast material during CT or MRI. It is important to realize that there are potential pitfalls with current CT and MRI techniques, because of the heterogeneous enhancement of the normal spleen during dynamic bolus imaging. As previously described, delayed scanning may be helpful, but occasionally, the lesions may enhance to the same level as the remaining spleen (Fig. 39-5).

In general, MRI is less reliable than CT, because both the normal spleen and lymphomatous tissue may have similar T1 and T2 relaxation times and proton densities.^{93, 122} Use of superparamagnetic iron oxide has been

proposed to improve detection of lymphoma lesions on MRI.¹³² If lymphoma is present in the liver, the spleen is practically always involved as well.¹¹⁴ Although rare, calcifications can be seen with splenic lymphoma both before and after treatment. They are most likely dystrophic calcifications secondary to necrosis, hemorrhage, and subsequent fibrosis.⁹³

The other role of cross-sectional imaging in patients with lymphoma is to differentiate between lymphoma and other disease processes. For example, patients with lymphoma may undergo chemotherapy and become immunocompromised and may thus be susceptible to disseminated fungal infections such as candidiasis. Fungal infections may be difficult to diagnose, and fungal microabscesses should not be mistaken for foci of splenic lymphoma. MRI with gadolinium enhancement has been shown to be an effective modality to differentiate between fungal abscess and lymphoma lesions.¹⁰⁸

Splenic abscess may demonstrate clinical and imaging features similar to those of lymphoma—that is, fever, left upper quadrant pain, malaise, and cystic lesions within the spleen. In general, splenic abscesses rarely occur with lymphadenopathy; this fact can be helpful in differentiating between these two entities.^{43, 93} Even with current imaging

Figure 39-5. Splenic lymphoma on MRI. These images demonstrate a pattern of gradual enhancement of splenic lymphoma after IV administration of gadolinium. *A*, T2-weighted MR image demonstrates lymphoma as low-signal foci relative to the normal spleen. Also present are bilateral pleural effusions. *B*, T1-weighted, portal venous phase MR image obtained after IV administration of gadolinium demonstrates lymphoma as partially enhancing, low-signal foci. *C*, T1-weighted MR image obtained 5 minutes after IV administration of gadolinium demonstrates gradual enhancement of the lymphoma foci to isointensity with the spleen.

technology, however, differentiating lymphoma from abscess can occasionally be difficult. For example, necrotic lymphoma lesions may appear cystic and look similar to splenic abscess. Although necrosis of lymphoma lesions is rare,⁹³ larger lesions can manifest as cystic-appearing masses or may have cystic components.¹²⁵ Gas within a cystic-appearing splenic lesion suggests infection, although gas can also be seen with necrosis only. Splenic infarcts may occur in conjunction with lymphoma. Typically, infarcts are peripheral, wedge-shaped lesions.

Splenic lymphoma may be associated with human immunodeficiency virus (HIV). Single or multiple low-attenuation foci may be present. Focal splenic lesions are more common in patients with lymphoma related to acquired immunodeficiency syndrome (AIDS) than in patients with lymphoma unrelated to AIDS.¹²³ The diagnosis of non-Hodgkin's lymphoma in a patient with HIV infection fulfills the criteria for the diagnosis of AIDS.¹²³ In general, AIDS-related lymphomas are aggressive and often manifest with multiple sites of abdominal involvement.¹²³

Splenic Angiosarcoma

Splenic angiosarcoma is a rare neoplasm of the spleen, which may be primary or metastatic. It has a poor prognosis and may be complicated by splenic rupture.²⁴ There

appear to be two types of angiosarcomas. Some angiosarcomas appear to be related to exogenous administration of substances such as thorium dioxide, vinyl chloride, and arsenic; they arise in the liver and can have a few metastases to the spleen. The angiosarcomas unrelated to such toxic substances arise in both the liver and the spleen.²⁴ Angiosarcomas can manifest as multiple nodules of various sizes or show permeative growth into the spleen; some may have hemorrhage.^{42, 93} Like hepatic hemangiomas, angiosarcomas may show varying degrees of enhancement.⁹³

Splenic Metastases

Although metastases to the spleen are more common than primary neoplasm, they tend to occur in patients with widely disseminated tumor. Primary tumors that commonly metastasize to the spleen include melanoma and lung, breast, and ovarian carcinomas. Direct invasion may also occur from gastric, pancreatic, or colon carcinoma (Fig. 39-6).

Cysts

Various types of focal lesions of the spleen may appear cystic on cross-sectional imaging. They include congenital

Figure 39-6. CT scans showing spleen metastases. *A*, Low-attenuation melanoma metastases to the spleen. *B*, Low-attenuation breast cancer metastases to the spleen, liver, and left adrenal gland. *C*, Ovarian carcinoma with cystic spleen and liver metastases (arrows). *D*, Ovarian carcinoma with calcified spleen and liver metastases after treatment (arrows).

(true) cysts, nonpancreatic pseudocysts (post-traumatic hematoma), cystic neoplasms (i.e., lymphangiomas, hemangiomas, lymphomas, and metastases), inflammatory lesions (abscesses and parasitic cysts), and vascular lesions (infarction, peliosis).^{32, 88, 126} Congenital cysts are generally classified as “true” cysts and contain an epithelial lining (also called epidermoid, epithelial or congenital cysts), whereas “false” cysts or pseudocysts do not have an epithelial lining.³² True cysts are believed to be developmental in origin. Possible explanations for the development of the epithelial lining include infolding of peritoneal mesothelium and collections of peritoneal mesothelial cells trapped within the splenic sulci.^{32, 37, 126} False cysts are presumed to be post-traumatic in origin, may be hemorrhagic or serous, and may be the end stage of intrasplenic hematoma.^{32, 88, 126} Post-traumatic false cysts probably account for 75% to 80% of all splenic cysts.^{88, 126} Because splenic cysts have been found in women of childbearing age, it is thought that congestion and infarction of the spleen during pregnancy cause hemorrhage and secondary cyst formation.³⁷

True and false cysts can appear identical on cross-sectional imaging. Typically, both are well-defined, homogeneous, and unilocular (although septations may be present). Although it may be impossible to differentiate between true and false cysts on imaging studies, there are a

few differential points to consider. False cysts, which tend to be smaller, have internal debris and peripheral calcifications.¹²⁶ Peripheral calcifications are less common in true cysts.³² The diagnosis of false cyst should also be favored when (1) there is a clear history of trauma, (2) the patient is older than the fourth decade, or (3) there is hematoma elsewhere in the spleen.³² On CT scans, both true and false cysts have an attenuation value near or equal to that of water, their walls are either thin or imperceptible, and they do not enhance after IV administration of a contrast agent (Fig. 39-7). On MRI, both types of cysts appear to contain fluid with a signal intensity similar to or slightly greater than that of water. After administration of gadolinium, the cysts show no central or rim enhancement.⁶⁵

It may be difficult to differentiate the various cystic lesions of the spleen. The clinical and imaging features may have to be considered together to narrow the differential diagnosis, which includes echinococcal cysts (which often appear multiseptated), large solitary abscess or hematoma (usually distinguished on basis of clinical history), and cystic neoplasms of the spleen.³²

Hemangioma

Splenic hemangioma is the most common benign splenic neoplasm. Its incidence is 0.03% to 14% in autopsy series.¹

Figure 39-7. CT scans showing splenic cysts. A, Splenic cyst with septations. B, Splenic cyst with peripheral calcifications.

Hemangiomas of the spleen may be single or multiple and may occur as part of a generalized angiomatosis (Klippel-Trenaunay-Weber syndrome).⁹⁶ Splenic hemangiomas are usually cavernous in subtype, although they may be capillary or mixed. Infarction, thrombosis, or fibrosis may occur in splenic hemangiomas, just as in hemangiomas in other parts of the body.⁹⁶

Solitary hemangiomas are usually asymptomatic and are often incidentally discovered in adults. Hemangiomas may grow slowly and, as they enlarge, can produce symptoms such as pain and fullness in the left upper quadrant. Up to 25% of splenic hemangiomas may manifest acutely because of rupture.⁹⁶ Anemia, thrombocytopenia, and coagulopathy (Kasabach-Merritt syndrome) have been reported with large hemangiomas, likely secondary to the sequestration of red cells and platelets and consumption of clotting factors.⁹⁸

On CT, solitary splenic hemangiomas are usually small and solid. However, larger hemangiomas may be more complex and may have both solid and cystic components. Rarely, central and punctate or peripheral and curvilinear

calcifications may be noted.⁹⁸ On nonenhanced scans, solid splenic capillary hemangiomas are typically isodense to hypodense relative to normal spleen; after IV administration of a contrast agent, they enhance from the periphery to the center, like hepatic hemangiomas (Fig. 39-8).⁹⁸ However, cavernous hemangiomas of the spleen tend to have mixed solid and cystic components, and unlike their classic appearance in the liver, they demonstrate discrete mottled areas of heterogeneous density on delayed images after administration of a contrast agent (Fig. 39-9).⁴²

Splenic hemangiomas have low signal on T1-weighted MR images and higher signal (> 120 msec) on T2-weighted images, particularly with prolonged TE. Complex hemangiomas may have mixed signal on T1- and T2-weighted images. After IV administration of gadolinium, splenic hemangiomas demonstrate peripheral enhancement with progressive central fill-in. Ramani and associates⁹⁶ found that 19 of 22 hemangiomas had peripheral enhancement with centripetal fill-in. Only two lesions in their series demonstrated a clearly defined peripheral nodular type of enhancement; the remaining lesions demonstrated a periph-

Figure 39-8. CT scans showing hemangioma of the spleen. A, Initial post-contrast image demonstrates a low-attenuation lesion (arrow). B, Delayed scan obtained at 3 minutes shows complete enhancement.

Figure 39-9. Hemangioma of the spleen, demonstrated on both CT and MRI. A. CT scan obtained during the arterial phase shows a heterogeneously enhancing hemangioma in the spleen (arrow). B. T2-weighted MR image demonstrates the heterogeneously high signal of the hemangioma. C. T1-weighted, portal venous phase MR image obtained after IV administration of gadolinium demonstrates heterogeneous enhancement of the hemangioma, similar to the CT appearance on A. D. T1-weighted MR image obtained 5 minutes after IV administration of contrast agent image demonstrates near-complete enhancement of the hemangioma.

eral rim of variable thickness with irregular inner margins. One hemangioma had central enhancement. Splenic hemangiomas also demonstrate retention of contrast material on delayed images, like hepatic hemangiomas. However, as described for CT, not all splenic hemangiomas have this classic pattern of enhancement on MRI (Figs. 39-10 and 39-11).

Differentiation of splenic hemangiomas from other splenic neoplasms can be difficult. Positive result of red blood cell scintigraphy can establish the diagnosis of hemangioma of the spleen.³⁹

Splenic Lymphangioma and Lymphangiomatosis

Lymphangiomas are rare, slow-growing, benign tumors composed of lymphatic vessels. Splenic lymphangiomas are considered very rare.⁴² They may be solitary but more often appear as multiple, thin-walled, well-marginated cysts that may be subcapsular in location.^{92, 129} When lymphangi-

omas are diffuse, their presence is called *lymphangiomatosis*.

The prognosis of isolated splenic lymphangioma or lymphangiomatosis is believed to be good. In some cases, however, the presence of splenic lymphangiomatosis may signal multisystem involvement, known as cystic angiomatosis, consisting of lymphangiomatous or hemangiomatous involvement of bone, soft tissues, and viscera. This multisystem form can be progressive and can have a poor prognosis.¹²⁹

On CT and MRI, splenic lymphangiomas appear as multiloculated cystic lesions that do not enhance on arterial or delayed phase imaging (Fig. 39-12).⁶⁵ Angiography demonstrates multiple, well-defined, avascular lesions of various sizes that give the spleen a “Swiss cheese” appearance.

Splenic Hamartoma

Rare lesions, splenic hamartomas are usually solitary masses. They are classified as white pulp or red pulp

Figure 39-10. MR images of the same patient showing hemangioma of the spleen. A, T2-weighted image shows a high-signal hemangioma (arrow) on prolonged TE (TR = 5046 msec, TE = 165 msec). B, T1-weighted image obtained 45 seconds after IV administration of gadolinium reveals that the hemangioma is low in signal and has not yet enhanced (arrow). C, On another T1-weighted image obtained 5 minutes after IV administration of gadolinium, the hemangioma retains contrast agent but does not completely enhance and has a mottled appearance.

hamartomas; most are a mixture of the two cell types.⁹⁶ They can be cystic or solid and may have punctate or stellate calcifications. Rarely, these tumors can be symptomatic, causing splenomegaly, pancytopenia, fatigue, and anorexia.¹²¹

On MRI, the solid lesions may be isointense on T1-weighted images and hyperintense on T2-weighted images relative to the spleen. Unlike hemangiomas, however, hamartomas do not demonstrate an increase in signal intensity similar to that of cerebrospinal fluid when images with higher T2 weighting (TE = 120 to 150 msec) are performed.¹²¹ After IV administration of a contrast agent, hamartomas demonstrate diffuse heterogeneous enhancement. Hamartomas may be difficult to distinguish from malignant lesions. Splenic hamartomas may demonstrate radiotracer uptake on sulfur colloid scintigraphy; this finding may be helpful in differentiating these lesions from malignant neoplasms and hemangiomas.

Infections and Diffuse Diseases

Splenic Abscess

Splenic abscesses are uncommon, having been reported in 0.14% to 0.70% of the large autopsy series.^{7, 25, 26} The observed rise in their incidence is believed to be due to an

increase in the number of immunocompromised patients, such as oncology patients undergoing current aggressive chemotherapeutic regimens, critically ill patients in intensive care units, and growing numbers of HIV-infected patients.³⁸ The development of a splenic abscess may require both bacteremia and intrinsic splenic disease that alters splenic architecture, such as infarct, hematoma, or sickle cell disease. Alternatively, splenic abscesses result from direct extension of infection from adjacent organs, such as the pancreas⁷² or the stomach.⁶⁷ Aerobic organisms account for 57% of splenic abscesses, with the majority being due to *Staphylococcus*, *Escherichia coli*, and *Salmonella*; 26% of abscesses are caused by fungi, predominantly *Candida*, and 18% by anaerobic organisms.⁸¹ The mortality rates range from 15% in otherwise healthy patients with unilocular splenic abscess to 80% in immunocompromised patients with multiple abscesses.³

On cross-sectional imaging, splenic abscesses may appear solitary or multiple. CT is the study of choice. The solitary abscesses and multiloculated abscesses tend to be bacterial. Septations may be present, and there may be an enhancing capsule. The CT appearance of an abscess may overlap with that of an infarct, hematoma, or neoplasm. The lack of mass effect helps differentiate infarct from abscess or other tumor. The presence of gas within the lesion is diagnostic of abscess; however this finding is rare. Gas is more readily apparent on CT than on MRI (Fig.

Figure 39-11. Atypical spleen hemangioma. This patient has multiple, atypical-looking splenic hemangiomas as well as a small type 3 liver hemangioma. *A*, T2-weighted MR image with long TE reveals the high signal small liver hemangioma (*arrow*) and the multiple atypical low-signal splenic hemangiomas (*arrowheads*). *B*, T1-weighted MR image obtained 5 minutes after IV administration of gadolinium shows delayed enhancement, with retention of contrast agent in the multiple splenic hemangiomas. The small liver hemangioma with contrast retention is located more superiorly. *C*, T1-weighted image obtained 5 minutes after IV administration of gadolinium at level just superior to that of *B*. The small liver hemangioma has type 3 enhancement (*arrowhead*) with incomplete enhancement. Additional splenic hemangiomas can be seen.

Figure 39-12. Multiloculated lymphangioma in the upper pole of the spleen, incidentally noted on a chest CT scan.

39-13). In patients with high surgical risk, percutaneous abscess drainage can be performed.

Multiple small splenic abscesses (microabscesses) are typically nonbacterial in origin and are most commonly associated with fungal infections. The liver is also usually involved. Fungal infections occur primarily in neutropenic patients, most commonly in patients with acute leukemia or other lymphoproliferative disorders who are undergoing high-dose chemotherapy with or without bone marrow transplantation.^{99, 108} An increase in the incidence of fungal abscesses of the spleen has resulted from the widespread use of aggressive chemotherapy.⁸¹ Prior to the development of helical CT and current MRI techniques, it was difficult to establish the diagnosis of hepatosplenic candidiasis. The lesions were often undetectable because of (1) their small size on imaging, (2) the often nonspecific clinical signs and symptoms, and (3) the commonly negative results of blood culture.^{73, 99} Percutaneous needle biopsy may also yield a false-negative result.⁸⁹ Typically, these lesions of hepatosplenic candidiasis are smaller than 2 cm, usually measuring 5 to 10 mm in diameter. However, they may also be less than 5 mm (miliary). On CT, they often have low attenuation (Fig. 39-14), although there can be a focus of high attenuation or a “wheel-within-a-wheel” pattern.

Figure 39-13. CT scans showing splenic abscesses. *A*, Unenhanced scan demonstrates a low-attenuation splenic abscess (arrows) with gas. *B*, Splenic abscess mass effect and complex fluid. *C*, Unenhanced scan shows two abscesses in the lower pole of the spleen (arrows).

MRI is the modality of choice to evaluate for hepatosplenic candidiasis. Semelka and colleagues¹⁰⁸ have described the appearance of hepatosplenic candidiasis on MRI, which they have used to distinguish the acute, sub-acute, and chronic phases of infection. Although MRI is very accurate in the diagnosis of acute hepatosplenic fungal disease, the findings may be falsely negative if the patient is neutropenic and is unable to mount an immune response to the infection.

Figure 39-14. Enhanced CT scan demonstrates multiple low-attenuation candidal microabscesses in this patient with chronic lymphocytic leukemia. A hepatic fungal microabscess is present as well.

Semelka and colleagues¹⁰⁸ described acute microabscesses as small (<1 cm), round lesions best demonstrated on T2-weighted images as hyperintense foci. On T1-weighted images, they are often poorly seen as low-signal foci and are only moderately demonstrated with gadolinium enhancement (Fig. 39-15).

After treatment, acute microabscesses become necrotizing granulomas with central abscess and peripheral fibrosis

Figure 39-15. T2-weighted MR image demonstrates multiple small foci of increased signal (arrows) in both the spleen and the liver consistent with acute fungal abscesses. The spleen and liver are diffusely decreased in signal because of iron overload from multiple transfusions.

surrounded by a zone of lymphocytes and macrophages. In the setting of multiple blood transfusions, the macrophages contain iron,⁶⁸ which produces a low-signal ring around the lesions on all MRI sequences. The lesions are still small, typically less than 1 cm in diameter. The subacute treated lesions are intermediate to mildly high in signal intensity on T1- and T2-weighted MRI sequences and have a perilesional ring nearly void of signal intensity.

If the therapy is successful, the subacute granulomas progress to chronic healed lesions composed of fibrous tissue of differing densities and degrees of vascularization. Chronic healed fungal abscesses are low in signal intensity on T1-weighted images and isointense to mildly hyperintense on T2-weighted images. They have an irregular polygonal shape and measure 1 to 3 cm in diameter. No perilesional dark ring is noted. These lesions are best noted on the early post-gadolinium images as moderately hypointense foci. They are minimally hypointense on delayed post-gadolinium images.

Other Infectious Processes

Other organisms, including *Mycobacterium tuberculosis*, *Mycobacterium avium-intracellulare*, and *Pneumocystis carinii*, may also infect the liver and spleen. Such infections tend to be miliary. *M. tuberculosis* infection can be seen in patients with immunodeficiency states associated with alcoholism, diabetes, steroid therapy, cancer, and HIV infection. Acutely, only splenomegaly may be present without focal lesions. Subsequently, microabscesses may form and may appear on CT as low-attenuation lesions. They may then progress to scattered punctate calcifications, innumerable calcifications throughout the spleen, and then to almost complete splenic calcifications.⁴⁶ In patients with HIV who have disseminated *M. tuberculosis*, the spleen is more commonly involved than the liver.⁸⁰

CT is the preferred modality for evaluation of disseminated processes such as mycobacterial infections, because other intra-abdominal manifestations, such as lymphadenopathy and bowel wall thickening, are better appreciated on CT than on MRI. Splenic microabscesses are generally intermediate in signal intensity on T1-weighted MR images and measure from a few millimeters to 1 to 2 cm in diameter. They may show ring enhancement after administration of gadolinium. On T2-weighted images, the microabscesses are high in signal intensity. As the lesions calcify, they become low in signal intensity on both T1- and T2-weighted images.¹²²

M. avium-intracellulare and *P. carinii* infections occur more commonly in patients with HIV infection. *M. avium-intracellulare* infection occurs as a late manifestation of AIDS. Differentiating between *M. tuberculosis* and *M. avium-intracellulare* can be difficult in patients with HIV. Focal splenic or hepatic lesions are noted in about 30% of patients with HIV who are infected with *M. tuberculosis* but are rarely noted in those infected with *M. avium-intracellulare* infection. Marked splenomegaly is more common in *M. avium-intracellulare* infection than in *M. tuberculosis* infection.^{80, 93, 94}

P. carinii infections occur very commonly in patients with AIDS, typically as pneumonia. However, with im-

Figure 39-16. CT scan in a 38-year-old man with acquired immunodeficiency syndrome shows multiple foci of *Pneumocystis carinii* in the spleen and liver.

provements in therapies for *P. carinii* pneumonia, extrapulmonary *P. carinii* has become more common. When involved, the spleen may be enlarged with focal lesions that may become progressively calcified either in a rimlike or punctate fashion over a few months.^{93, 95} However, not all lesions demonstrate calcification, even at follow-up (Fig. 39-16).⁹⁵

Peliosis

Peliosis is a rare disorder characterized by multiple blood-filled spaces that may involve the liver and spleen. It can lead to portal hypertension and organ rupture.^{75, 113} The disorder is associated with some drugs, including anabolic steroids and corticosteroids. However, peliosis is primarily associated with HIV and AIDS. In patients with AIDS, visceral peliosis is due to infection by *Bartonella henselae*, a treatable manifestation of AIDS. Infection by *B. henselae* affects multiple organ systems, including the skin, airway, mucous membranes, visceral organs, bone, and brain.⁷⁷ Kaposi's sarcoma may have a similar presentation in patients with AIDS. If Kaposi's sarcoma is clinically suspected in patient with AIDS, the treatable infection bacillary angiomatosis should be considered in the differential diagnosis.⁷⁷

In bacillary angiomatosis, multiple, blood-filled cavities ranging in size from a few millimeters to 1 to 2 cm are noted in the liver and spleen. Such cavities may or may not have an endothelial lining and may communicate with dilated sinusoids.⁹⁴ Some of the cavities may be thrombosed. The imaging findings depend on the pathologic appearance. On CT, the liver lesions appear as multiple small, low-attenuation foci that become isodense with IV administration of a contrast agent, whereas the splenic lesions can be variable, ranging from nonenhancing hypodense nodules up to 1.5 cm in diameter to nodules with a target appearance and central enhancement. The thrombosed cavities remain low in attenuation with contrast enhancement.^{75, 94} On MRI, multiple foci may be seen,

with increased signal intensity on T2-weighted images and variable signal intensity on T1-weighted images. The thrombosed cavities may show mixed signal on T2-weighted images because of the presence of deoxyhemoglobin and methemoglobin.⁷⁵ The diagnosis can be confirmed histologically.⁷⁶

Sarcoidosis

Sarcoidosis is a systemic disease of unknown etiology. It involves primarily the thorax (mediastinal and hilar lymph nodes and lung parenchyma), skin, and eyes. Less commonly it involves the liver and spleen. Mesenteric and retroperitoneal lymph nodes can also be involved. The appearance can be similar to that of lymphoma, particularly non-Hodgkin's lymphoma, and to metastases. However, involvement of retrocrural nodes by sarcoidosis is rare. This feature may help distinguish sarcoidosis from non-Hodgkin's lymphoma, in which retrocrural node involvement is common.

The most common finding is nonspecific hepatosplenomegaly, although sarcoidosis may also manifest as nodular lesions.¹⁰⁷ Scott and associates¹⁰⁷ evaluated the various patterns of nodular hepatosplenic sarcoidosis. They found the single most common pattern of nodular involvement to be isolated splenic involvement. The other patterns, listed in order of frequency, were hepatosplenic involvement with splenic predominance, comparable hepatic and splenic involvement, and isolated hepatic involvement. Hepatosplenic involvement with hepatic predominance was the least common presentation.

On CT, the nodules of sarcoidosis are low in attenuation without contrast enhancement (Fig. 39–17).^{60, 107} On MRI, nodular sarcoidosis has been described as having multiple low-signal intensity foci on T1- and T2-weighted images and no substantial enhancement.^{122, 130}

Hydatid Disease

Splenic involvement is uncommon in hydatid disease, occurring in less than 2% to 8% of all patients with

Echinococcus.^{45, 90} The liver, lung, bone, and brain are more commonly affected than the spleen. Systemic dissemination and intraperitoneal spread from a ruptured liver cyst constitute the two main sources of spread to the spleen.⁴⁵ Hydatid cysts are not often seen except in areas where *Echinococcus* is endemic, such as Argentina, Greece, and Spain.¹²⁶

The appearance of splenic hydatid cysts varies according to the age of the cyst and the associated complications, such as rupture and secondary infection. On CT, an uncomplicated cyst may have homogeneous fluid content with water attenuation; however, such a cyst may also contain debris, hydatid sand, or inflammatory cells that can cause high attenuation.⁴⁵ Peripheral calcifications may also be present. Classically, small daughter cysts, formed by invaginations of the inner layer of the cyst, are noted at the periphery of the main cyst.¹²⁶

Hydatid cysts are prone to rupture. Although rupture can be clinically silent, there are many potential complications, including anaphylaxis, infection, peritoneal seeding, perforation of hollow viscera, and hematogenous spread.⁹⁰ Infection can occur if there is cyst rupture. Infected cysts may appear solid, may have a mixed solid and cystic pattern, or may contain air or air-fluid levels. CT and ultrasonography are the most useful modalities for diagnosis, with CT being preferred in cases of suspected infection.⁹⁰

Splenomegaly

There are numerous causes of splenomegaly. Although CT or MRI can accurately determine splenic volume, the cause of the splenomegaly may not always be apparent from imaging alone. Splenomegaly can be due to congestion (e.g., portal hypertension, splenic vein thrombus), storage disease (i.e., Gaucher's disease, histiocytosis, amyloid), infection (i.e., infectious mononucleosis, tuberculosis), hematologic disorders (i.e., myelofibrosis, polycythemia vera), or neoplasms (i.e., leukemia, lymphoma). Splenomegaly is a nonspecific finding, but some of the possible causes of massive splenomegaly are chronic myelogenous leukemia, lymphoma, polycythemia vera, myelofibrosis, and chronic malaria (Fig. 39–18).¹¹⁷

Figure 39–17. CT scans showing sarcoidosis of the spleen. A, Multiple small, nonenhancing foci of sarcoidosis in the spleen. The liver is not involved. B, Diffuse involvement of the spleen by sarcoid. The lesions are nonenhancing, and splenomegaly is present.

Figure 39-18. This CT scan reveals massive splenomegaly in a patient with non-Hodgkin's lymphoma.

Portal Hypertension

Portal hypertension is a frequent cause of splenomegaly. In addition to splenomegaly, there is enlargement of the splenic vein, formation of varices, and formation of gamma-gandy bodies, which are small remnants of intrasplenic hemorrhage composed of hemosiderin, fibrous tissue, and calcium.¹²² On MRI, the gamma-gandy bodies are low in signal on T1- and T2-weighted images, appearing as multiple foci of signal void (Figs. 39-19 and 39-20).

Gaucher's Disease

Gaucher's disease is a metabolic disorder in which glucocerebroside accumulates abnormally in the reticuloendothelial system because of a deficiency of the enzyme glucocerebrosidase. Affected patients have hepatosplenomegaly, thrombocytopenia, and anemia. In one study, focal lesions were described on MRI in 30% of 46 patients with Gaucher's disease.⁵⁹ Both red and white types of nodules were noted. The white foci of solid Gaucher cells in the

spleen were judged to be isointense on the T1-weighted images and low in signal on T2-weighted images, but the red focal lesions contained sinusoids and behaved more like hemangiomas, showing increased signal on T2-weighted images.⁵⁹ Infarcts were also noted.

Hemochromatosis

Hemochromatosis results from iron deposition in multiple organs, including the spleen. Primary hemochromatosis, an autosomal recessive disorder, causes organ damage such as cirrhosis and possible hepatocellular carcinoma. Secondary hemochromatosis is caused by deposition of iron into the reticuloendothelial system (spleen, bone marrow, liver Kupffer cells), usually from blood transfusions or rhabdomyolysis. On MRI, a decrease in signal intensity is seen on both T1- and T2-weighted images because the tissue iron is superparamagnetic (Fig. 39-21).

Trauma

The abdomen is one of the most frequently injured sites in both blunt and penetrating trauma; the spleen is the most commonly injured organ. A missed splenic injury is one of the most common causes of preventable death in patients with trauma.¹³³ Iatrogenic splenic injuries also occur, the most common being intraoperative injury. The spleen may also be inadvertently injured during percutaneous needle procedures, such as left thoracentesis, kidney biopsy, and colonoscopy.¹¹⁸

Splenic injuries due to blunt trauma are produced by (1) rapid deceleration with compression through the posterolateral chest wall, in which energy is transmitted to the spleen, or (2) a puncture of the spleen through adjacent rib fractures. The forces on the spleen result in capsular avulsions along the various ligamentous attachments. Because 5% of the cardiac output goes to the spleen, which has an extensive arterial supply, injuries to the spleen can cause significant hemorrhage.

Figure 39-19. Portal hypertension, splenomegaly, and gamma-gandy body on MR images. A, T1-weighted image reveals massive splenomegaly. A gamma-gandy body is noted as low-signal, nonenhancing focus (arrow). B, T2-weighted image shows that the gamma-gandy body is low in signal (arrow).

Figure 39-20. MR images showing multiple gamma-gandy bodies. A, T1-weighted image demonstrates multiple low-signal foci in the spleen consistent with gamma-gandy bodies. There is also an enhancing hepatocellular carcinoma in the liver (arrow). B, T2-weighted image reveals the low-signal splenic gamma-gandy bodies.

The clinical evaluation of the abdomen by physical examination may be limited at times because of a patient's altered mental status due to head trauma, alcohol, or drugs. A patient with labile blood pressure and tachycardia should be rapidly assessed for intra-abdominal blood with either diagnostic peritoneal lavage (DPL) or abdominal ultrasonography (FAST [focused assessment with sonography for trauma]; see later); if blood is detected, the patient must undergo surgery immediately. More stable patients may be evaluated for splenic injury by DPL, FAST, or CT scanning. Hemodynamically stable patients are often initially evaluated with ultrasonography. If free fluid is detected on ultrasonography, an abdominal CT scan is obtained to identify the source of bleeding, search for other intra-abdominal injuries, and determine the severity of the splenic injury.

The key to patient management involves grading the splenic injury after review of the CT images or careful inspection of the mobilized spleen in the operating room. The revised 1994 American Association for the Surgery of Trauma (AAST) standard for grading of splenic injury has

now been adopted universally to facilitate clinical investigation and outcomes research (Table 39-1)⁷⁷; the grades are as follows:

Grade I: A subcapsular hematoma involving less than 10% of the splenic surface area or a laceration less than 1 cm deep.

Grade II: A subcapsular hematoma involving 10% to 50% of the splenic surface area, an intraparenchymal hematoma less than 5 cm in diameter, or a laceration 1 to 3 cm deep that does not involve a trabecular vessel.

Grade III: A subcapsular hematoma involving more than 50% of the splenic surface area, ruptured subcapsular or parenchymal hematoma, intraparenchymal hematoma greater than 5 cm, or a laceration more than 3 cm deep or involving the trabecular vessels.

Grade IV: A hilar laceration and devascularization of more than 25% of the splenic mass.

Grade V: A shattered or early completely devascularized spleen.

The decision to proceed to surgical intervention is multifaceted and depends on more than the results of any radiologic test. Generally, however, most patients with grade IV or grade V injuries require surgery. Patients with active extravasation may require endovascular or surgical intervention, even for grade II or III injuries.⁴⁰

Figure 39-21. A T2-weighted MR image demonstrates diffusely decreased signal intensity of the spleen in this patient who has received multiple transfusions (TR = 5000 msec, TE = 83 msec).

Goals and Strategy

The initial emergency room evaluation for any patient who has experienced trauma involves stabilization and resuscitation according to Advanced Trauma Life Support (ATLS) guidelines.

Patients with a splenic injury are ideally managed at a trauma center with experience in all of the therapeutic options. At many centers, CT is considered the standard for evaluation for trauma. However, many centers also employ FAST in the emergency department setting.

Table 39–1. Splenic Injury Scale of the American Association for the Surgery of Trauma

Grade*	Type of Injury	Description
I	Hematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, \leq 1-cm parenchymal depth
II	Hematoma	Subcapsular, 10–50% surface area; intraparenchymal, <5 cm in diameter
	Laceration	1–3-cm parenchymal depth that does not involve a trabecular vessel
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma; intraparenchymal, >5 cm or expanding
	Laceration	>3-cm parenchymal depth or involving trabecular vessels
IV	Laceration	Laceration involving segmental or hilar vessels producing major devascularization (>25% of spleen)
V	Laceration	Completely shattered spleen
	Vascular	Hilar vascular injury that devascularizes spleen

* Advance one grade for multiple injuries, up to grade III.

From Moore EE, Cogbill TH, Jurkovich GJ, et al: Organ injury scaling: Spleen and liver (1994 revision). *J Trauma* 38:323–324, 1995.

Focused Assessment with Sonography for Trauma

A limited form of ultrasonography known as FAST has emerged as a new modality for the assessment of the injured torso. The 1992 introduction of this modality with the first published study in the United States rapidly changed the assessment of the trauma patient, so that by 1999, 79% of Level I trauma centers utilized FAST.^{10, 124}

The use of ultrasonography as a FAST examination is indicated in the initial trauma evaluation of patients in whom there is a concern about intraperitoneal blood. The most important application is in the evaluation of hemodynamically unstable patients who have multiple injuries, so that a quick decision regarding surgery can be made. The place for ultrasonography in stable patients is less clear. In such patients, CT scanning is important for staging the injury because nonoperative management has become so prominent.

Technique

The FAST examination is performed as part of the primary survey in hemodynamically unstable patients or during the secondary survey in the trauma resuscitation area. This procedure evaluates for the presence of fluid in the following four areas: the subxiphoid region for the pericardial sac; the right upper quadrant in Morison's pouch; the left upper quadrant in the splenorenal recess; and the pelvis in the pouch of Douglas. The examination is performed in these four areas for the specific purpose of identifying hemoperitoneum or tamponade. It can be done at the patient's bedside at the same time as other procedures or evaluations. With the use of real-time imaging, physicians can receive instantaneous information to augment the trauma examination.

The stable patient with a negative FAST result is followed clinically rather than evaluated with CT. The stable patient with a negative FAST result who has a high-energy pelvic ring fracture, the seatbelt sign, or a significant head injury may require abdominal CT.^{6, 109} The stable patient with a positive FAST result should undergo a CT scan for grading of the splenic or liver injury. Generally, the unstable patient with a positive FAST result requires urgent exploratory laparotomy.

Efficacy

The sensitivity of FAST ranges from 85% to 99% with a specificity of 97% to 100%. False-negative results occur with retroperitoneal and hollow viscus injuries. Bode and colleagues⁹ used ultrasonography to evaluate 353 patients with blunt trauma and found the technique to have 93% specificity and a 99% accuracy rate.⁹ Rothlin and associates¹⁰⁰ reported that ultrasonographic assessment of intra-abdominal injuries in 290 patients had a sensitivity of 90% and a specificity of 99%.¹⁰⁰

Boulanger and coworkers¹⁰ reported in 1999 on their review of the utilization of the FAST examination. A survey of 96 Level I trauma centers in the United States and Canada found that 79% routinely use FAST; the examination is performed by surgeons in 39% of institutions, by surgeons and emergency departments in 21%, by emergency departments in 5%, and by radiologists in 35%.¹⁰ The introduction of FAST has also changed management of patients with trauma in that CT scans and DPL are now used less for initial management.

The advantages of FAST are as follows: (1) it can be performed immediately at the bedside, making evaluation of the patient more efficient, (2) it is inexpensive, (3) it is noninvasive, and (4) it can be easily repeated. Its disadvantages involve the fact that it is examiner dependent. Assessment can be more difficult in the obese patient, the patient with significant subcutaneous emphysema, or the patient with a large volume of bowel gas interposed between the spleen and the abdominal wall. The FAST examination also has a lower sensitivity for free fluid volumes less than 500 mL. Ultrasonography can miss a solid organ injury that is not actively bleeding. The abdominal evaluation cannot grade splenic injuries. Other important injuries, such as bowel perforation, pancreatic fracture, and retroperitoneal injuries, may not be detected by ultrasonography.¹⁰⁹

CT Scan

CT scanning is still the most common means of evaluating the abdomen in stable patients with blunt abdominal trauma, although the use of ultrasonography is rapidly increasing. The overall diagnostic accuracy of CT scanning is approximately 95%.^{41, 66} The goals are to ascertain a diagnosis, to categorize the injury, and to reliably rule out

other concomitant injuries in the management of the patient who has sustained blunt trauma to the abdomen. The indications for an abdominal CT scan are blunt trauma, hemodynamic stability, unreliable physical examination, and assessment for duodenal and pancreatic trauma because of the mechanism of injury. Contraindications for abdominal CT scans include clear indications for exploratory laparotomy, hemodynamic instability, and severe agitation.

State-of-the-art helical CT scans can very rapidly image the head, chest, abdomen, and pelvis as needed. Typically, a contrast agent is given both orally and intravenously as a bolus with a mechanical injector. The patient receives 400 mL of a dilute (2% to 5%) water-soluble contrast agent orally or through a nasogastric tube at least 30 to 50 minutes prior to the scan, usually while still in the trauma room. Once positioned inside the CT scanner, the patient should be given 100 mL of Optiray 240 (ioversol 51%, 240 mg I/mL) intravenously, at a rate of 2 to 3 mL per second via an automated injector, 45 to 60 seconds prior to image acquisition. Images obtained too early after the bolus of IV contrast agent is started often show heterogeneous enhancement of the spleen because of differential enhancement of the red and white pulp. Splenic lacerations may not be visualized during this phase of enhancement. If the spleen demonstrates this type of enhancement or if corticomedullary differentiation is still noted in the kidneys, delayed scans should be performed. Ideally, delayed scans should be performed within 2 to 3 minutes after initiation of the IV bolus. Uncooperative patients should be sedated to minimize motion artifacts.

Ideally, the presence of an experienced radiologist at the time of the scan will greatly enhance the value of the study. Injured patients are often imaged while still on a fracture board and with monitor wires overlying them; the board and wires can cause multiple artifacts on the images. Care should be taken to avoid misinterpreting such an artifact as a laceration. The entire abdomen and pelvis should be evaluated. Usually, the appearance of free abdominal fluid without solid organ injury on a CT scan should raise the suspicion of mesenteric, intestinal, or bladder injury, and an exploratory laparotomy may be warranted. Subtle signs of bowel injury should also be assessed, such as free intraperitoneal air, focal wall thickening, and mesenteric edema or fluid.¹¹⁵

Splenic subcapsular hematomas may be isodense to the spleen on nonenhanced CT scans. They are better visualized after IV administration of a contrast agent because they do not enhance unless there is active hemorrhage. Most subcapsular hematomas have some mass effect on the adjacent splenic parenchyma; this finding differentiates them from perisplenic hematomas, which do not deform the spleen. Splenic lacerations are linear, low-attenuation parenchymal defects. A *fracture* is a laceration traversing two capsular surfaces. Multiple lacerations and fractures appear as a shattered spleen. Intraparenchymal hematomas appear as low-attenuation, rounded areas. Lack of enhancement of part or all of the spleen suggests injury or thrombosis of the splenic artery or segmental artery (Fig. 39–22). In addition to the size of the splenic injury, the presence of active bleeding should be assessed. *Active bleeding* is defined as CT evidence of focal intrasplenic or perisplenic collection that has attenuation values similar to those of

the aorta or a major adjacent artery and greater than the attenuation value of the spleen.^{40, 49, 110} As stated previously, the presence of active bleeding may necessitate surgery even for a relatively low-grade splenic injury.⁴⁰

Although most splenic injuries are well demonstrated on CT, there are various sources of false-negative and false-positive interpretations. A perisplenic clot (*sentinel clot*) may be seen with splenic injury. Both hemoperitoneum and a sentinel clot may be noted in cases of splenic injury without obvious visualization of a laceration.¹³⁴ Sources of potential false-positive interpretations include congenital clefts, splenic cysts, beam-hardening artifacts, and images obtained too early after the IV contrast bolus is given. Congenital clefts through the spleen should not be mistaken for lacerations. Splenic clefts are common variants. They can occur anywhere but tend to be in the superomedial aspect of the spleen (see Fig. 39–1). A lack of perisplenic hematoma would suggest a congenital cleft and not a laceration. Splenic cysts are usually spherical and low in attenuation.

A prospective multi-institutional study found that patients with negative abdominal CT scan results do not require the usual 24 to 48 hours of hospitalization for observation.⁷⁴ The initial abdominal CT scan had a negative predictive value of 99.63% on the basis of the subsequent need for laparotomy. This excellent study of more than 2000 patients showed that even a patient with abdominal tenderness could be sent home if CT scan results are negative, because CT scan findings are diagnostic for the presence or absence of abdominal injury but physical examination findings are not.

However, delayed rupture of the spleen can occur up to 10 days after injury. This complication is believed to be associated with subtle low-grade injury to the spleen that is not detectable on CT, ultrasonography, or DPL.⁷¹ The exact incidence of delayed rupture of the spleen is not known.

Diagnostic Peritoneal Lavage

DPL, initially described in 1965, was the standard diagnostic procedure for blunt trauma for the next two decades.⁶⁰ The procedure is a rapid and accurate test used to identify intra-abdominal injuries in patients who are hypotensive or are unresponsive after incurring blunt trauma to the abdomen but who have no obvious indication for abdominal exploration.

Indications include equivocal physical findings, unexplained shock, altered sensorium, and general anesthesia for extra-abdominal procedures. DPL is still indicated (1) for the unstable patient with an indeterminate FAST result and (2) to rule out a bowel injury in the stable patient in whom FAST and CT scans show free fluid with no solid organ injury. Contraindications to DPL include a clear indication for exploratory laparotomy. Some relative contraindications are previous exploratory laparotomy, pregnancy, and obesity.

DPL is highly sensitive to the presence of intraperitoneal blood, with sensitivities approaching 99%; however, its specificity is lower. Significant injuries that can be missed

Figure 39-22. CT scans showing classification of trauma to the spleen. **A**, Grade I injury: A small subcapsular hematoma (arrows) can be seen in a patient with an enlarged spleen from chronic lymphocytic leukemia. There is also a left pleural effusion. **B**, Grade II injury: A 4-cm intraparenchymal hematoma (arrow) and a 30% subcapsular hematoma (arrowhead) are seen in a patient after a fall. **C**, Grade II injury: A 3-cm laceration without involvement of trabecular vessels is shown in the lateral aspect of the spleen. **D**, Grade III injury: There is a 4-cm laceration near the hilum. **E**, Grade IV injury: Hilar laceration with devascularization of approximately 50% of the spleen can be seen. **F**, Grade V injury: The spleen is shattered, and only minimal parenchyma remains.

by DPL include retroperitoneal hematomas and diaphragmatic tears as well as renal, pancreatic, duodenal, and extraperitoneal bladder injuries. DPL may give false-positive results in the presence of a pelvic fracture, because of bleeding from the retroperitoneum into the peritoneal cavity.

The major advantage of DPL is that it requires no specialized equipment and is a rapid, sensitive technique to determine whether there is intraperitoneal blood. As CT began to be utilized, it became apparent in some hemodynamically stable patients, small splenic injuries could cause a positive DPL result and lead to nontherapeutic laparotomy. In other words, for stable patients, DPL was too sensitive.

Nonoperative Management

Blunt traumatic injury to the spleen is no longer considered to require immediate exploratory laparotomy. The lifelong susceptibility of these patients who have undergone surgery to infectious complications has prompted splenic conservation whenever safe and feasible. In most hemodynamically stable patients with blunt splenic trauma, management has evolved from splenectomy to splenorrhaphy to nonoperative management. Nonoperative management is not an easy approach, however, because it requires close monitoring, serial clinical examinations, and a high level of vigilance and familiarity with the course of splenic injuries. The goal is to preserve the spleen's role in the immune system and to save the patient the morbidity of exploratory surgery.

The spleen's anatomy holds the key to successful observation in splenic injury. In children, the splenic capsule is relatively thicker than in adults and can contract, thus leading to tamponade. This ability lessens with age as the vessels harden, making the spleen more friable in older patients. The spleen in such patients has a thinner capsule and is less able to contract, so observation as treatment is less successful in older patients with blunt splenic injury.

Pediatric patients were the first to benefit from the nonoperative approach to splenic injuries, with success

rates of 97%.⁶⁵ In the 1990s, the success rate for nonoperative treatment of hemodynamically stable adult patients with blunt splenic injuries exceeded 90%. Such treatment has always been less successful than in adults in children, probably because of (1) the greater severity of adult injuries and (2) the higher number of associated extra-abdominal and intra-abdominal injuries in adult patients, which preclude a nonsurgical approach in patients with injured spleens (Fig. 39–23).⁹¹

Angiography

Angiography has become an integral part of the nonsurgical armamentarium available for the care of the patient with trauma. In the appropriate setting, angiography is indicated for such patients in whom contrast extravasation and active hemorrhage are demonstrated on initial CT scan. If a bleeding vessel or pseudoaneurysm is noted, embolization can be performed. Scalfani and associates¹⁰⁴ have documented a splenic salvage rate of 93% to 97%. Pachter and colleagues⁸⁶ report a 98% salvage rate with no mortality for the use of angio-embolization if (1) active hemorrhage is detected on initial CT scan, (2) the patient's hematocrit drops, or (3) a new or worsening injury is demonstrated on a second CT scan. Selective arteriography is relatively contraindicated in patients with hemodynamic instability, peritonitis, or other indications for emergent surgery. It remains unclear whether splenic artery embolization has any detrimental effect on the spleen's immune function.

Splenic Infarcts

Splenic infarcts occur commonly and have various causes. The splenic arterial branches are end arteries with no intercommunication. Causes of splenic infarcts include embolic disease (i.e., mitral valve disease, endocarditis, atheromatous plaques), arteritis, splenic artery aneurysm or occlusion (pancreatic disease), sickle cell disease (thrombo-

Figure 39–23. CT scans following the conservative management of a grade III splenic injury in an adult. *A*, Initial CT scan demonstrates a grade III injury with a large subcapsular hematoma and a 5-cm laceration. *B*, Follow-up CT obtained at 3 months shows complete healing.

Figure 39-24. CT scans and angiogram showing the various appearances of splenic infarct. A, CT angiogram with a parasagittal reconstruction reveals a thrombus in the aortic arch (arrow), which caused an acute embolic splenic infarct (shown in B). B, Acute embolic infarct (arrow) with left pleural effusion (arrowhead). C, A splenic artery pseudoaneurysm (arrow) in a patient with pancreatitis caused a splenic infarct (shown in D). D, A splenic infarct due to the splenic artery pseudoaneurysm shown in C. E, Splenic infarcts (arrows) and splenic vein thrombus (arrowhead). F, Splenic infarct and splenomegaly in a patient with lymphoma. G, Multiple splenic infarcts simulating a mass. (Figure continues.)

Figure 39-24. Continued. *H* and *I*, Evolution of a splenic infarct. The acute splenic infarct (*H*) heals to become fissure-like (*arrow*) at 9-month follow-up (*I*).

sis), or mass lesions. Most cases are asymptomatic, although some patients have acute onset of left upper quadrant pain. The infarcts are typically focal but can be diffuse. Infarcts in younger patients are due more often to thrombosis from a hematologic disorder; infarcts in older patients tend to be embolic (Fig. 39-24).

On CT and MRI, infarcts are usually wedge-shaped but may be irregular in contour. Although the infarct has no enhancement, there can be peripheral enhancement of the capsule. Infarcts can also be multiple. As described previously, differentiating between infarct and abscess or tumor can sometimes be difficult. A lack of mass effect and perisplenic changes suggests infarct. Over time, infarcts decrease in size. Any increase in size would be suspicious for superimposed infection. On MRI, the signal of the infarct can vary, depending on its composition and age.⁶⁵ Hemorrhagic infarcts may be high in signal on T1- and T2-weighted images.⁶⁵

Chronic splenic infarction, as seen in homozygous sickle cell anemia, leads to near-complete calcification and atrophy of the spleen. Adults with heterozygous hemoglobinop-

athies may have enlarged spleens with subcapsular calcification (Fig. 39-25).

Miscellaneous Disorders of the Spleen

Splenosis

Splenosis is caused by autotransplantation of splenic tissue. It usually occurs after trauma. The implants are located throughout the peritoneum. The diagnosis can be confirmed by a nuclear medicine heat-damaged red cell scan.

Inflammatory Pseudotumor

Inflammatory pseudotumor of the spleen is a rare, benign lesion composed of localized areas of inflammatory cells.⁶⁴ The etiology is uncertain. On CT, such areas are

Figure 39-25. CT scans in sickle cell disease. *A*, Calcified, shrunken spleen in a patient with homozygous sickle cell anemia (*arrows*). *B*, Scan in an adult patient with homozygous sickle cell anemia and nearly complete splenic calcification, with a subcapsular hematoma (*arrows*), after undergoing exploratory laparotomy. The liver is also diffusely increased in attenuation, suggesting iron overload.

low in attenuation on nonenhanced images and show progressive opacification after IV administration of a contrast agent.⁹³ Calcifications may be present. Inflammatory pseudotumors have been described as being low in signal on T2-weighted MR images with delayed enhancement on T1-weighted images after IV administration of gadolinium; however, because there are few reports, the imaging characteristics of these lesions have not been established.⁶⁴

The Adrenal Glands

Timothy J. Welch, Patrick F. Sheedy II

The adrenal glands play an important role in endocrine function. First described by Eustachius in 1563, they continued to be studied over the next 400 years until the 20th century, when their important endocrine and physiologic functions were defined. More recently, powerful imaging techniques such as ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) have played an important role in defining pathologic conditions of the adrenal glands. This has resulted in remarkable advances in our understanding of the normal physiology and pathologic states involved in adrenal disease.

Normal Anatomy

The adrenal glands develop from mesenchyme adjacent to the urogenital ridge and appear in the fetus at the 7- to 8-mm stage.¹³ By the time the fetus reaches the 20- to 25-mm stage, a distinction between the two zones of the adrenal glands can be made. When the baby is born, the adrenal glands weigh approximately 5 g each. They then undergo involution over the next several weeks. This fall in weight is secondary to degeneration of the fetal zone within the cortex.⁷³ Maturation of the cortical and medullary portions of the adrenal gland generally occurs within the first several years of life.

The right adrenal gland is located in an area just superior to the right kidney, medial to the right lobe of the liver, lateral to the crus of the right hemidiaphragm, and posterior to the inferior vena cava. Its shape is variable but may resemble an elongated comma lying in the crease between the liver and the crus of the diaphragm (Fig. 40-1). It also may be shaped like an inverted letter V or Y. The lateral limb of the adrenal gland lies close to the right lobe of the liver and can sometimes be difficult to separate from the surface of the liver.

The left adrenal gland is located above and extends anterior to the upper pole of the left kidney in a triangle formed by the left lateral margin of the aorta, the posterior surface of the body and tail of the pancreas, and the anterior superior medial surface of the upper pole of the left kidney (Fig. 40-2). It is shaped like an inverted letter V or Y or an inverted or reversed letter L. It may also be triangular.

The right adrenal gland is usually in a clearly suprarenal location in the retroperitoneum, whereas the position of the left adrenal gland in the retroperitoneum is frequently in front of the anterior surface of the left kidney. The superoinferior length of the gland is variable but can extend from 2 to 6 cm. The right gland maintains a constant relationship with the posterior surface of the inferior vena cava. Its lateral limb is known to extend more inferiorly than the

medial limb. The superior portion of the left gland, behind the pancreas, often abuts the splenic vessels, and its inferior margin extends to the superior aspect of the left renal vein.

The normal adult adrenal gland weighs approximately 4 g in both men and women.^{13, 59} Its outer cortex, which is yellow, surrounds an inner medulla, which is pale gray. The medulla, which is usually absent from the tail of the glands, generally makes up between 10% and 20% of the total weight of the adrenal gland. The degree of thickness of the adrenal cortex overlying the medulla varies according to location, and at times it can be difficult to distinguish between the two zones.

The adrenal glands have a unique blood supply, in that they are supplied by multiple arteries, including branches from the inferior phrenic artery, aorta, and ipsilateral renal artery.¹⁵ These arteries branch to form a vascular plexus just beneath the capsule of the adrenal gland. A great degree of variability exists in the arterial supply to the adrenal glands. The venous drainage of the right adrenal gland differs from left to right. The right adrenal vein drains directly into the inferior vena cava between the right renal vein and the hepatic veins. The left adrenal vein joins the left renal vein several centimeters away from the inferior vena cava. Thus, the unique blood supply, together with the vascular nature of the adrenal gland, plays an important role in the imaging characteristics of adrenal abnormalities and their appearance at biopsy.

The apparent thickness of both adrenal glands depends on their orientation relative to the plane of imaging. They appear thicker if obliquely oriented and thinner if vertically oriented in transaxial images. Rarely does the thickness of a normal adrenal gland exceed 10 mm; more commonly, the gland is 5 to 6 mm thick. Variability in the appearance of the glands is due to differences in abdominal fat content, the orientation of the glands with respect to the plane of the scan, and differences in anatomic location.

Adrenal Physiology

The adrenal glands are made up of two distinctly functioning portions: the adrenal cortex and the adrenal medulla.

Cortex

The adrenal cortex synthesizes three main groups of hormones: glucocorticoids, mineralocorticoids, and adrenal androgens.⁴⁹ All of these are derived from cholesterol and share a common structural formula.

The cortex is divided into three zones: the zona glomer-

Figure 40-1. Normal adrenal glands. *A*, Typical location and appearance of the right gland (*black arrow*), which is shaped like an upside-down V. On the left, the gland is located in a triangle bounded by the pancreas, aorta, and kidney. It is shaped like an upside-down Y (*white arrow*). *B*, Magnification view of the same scan shows the medial (*white arrows*) and lateral (*black arrows*) limbs of the gland to better advantage. The limbs are thinner than the apex of the gland.

ulosa, the zona fasciculata, and the zona reticularis. Steroid synthesis differs in each zone. The zona glomerulosa is a major source of glucocorticoids. The zona fasciculata and the zona reticularis are thought to act as a unit in the production of cortisols and androgens. Unique to the zona fasciculata are large, clear lipid-laden cells. The degree to which the zona fasciculata is present plays an important role in the imaging characteristics of many adrenal lesions.

Medulla

The adrenal medulla is derived from neuroectodermal tissue and contains catecholamine-producing cells known as chromaffin cells.¹³ The primary catecholamines produced by the adrenal medulla include norepinephrine and epinephrine. These chemicals act primarily on the α -adrenergic and β -adrenergic receptors present in the body. The main endocrine effects of these catecholamines are in the cardiovascular system and in glucose metabolism.

Imaging Modalities

Imaging of the adrenal glands can be accomplished via many different modalities, including plain films, ultrasonography, nuclear medicine imaging, CT, and MRI. In recent years, CT and MRI have become the imaging modalities of choice in adult patients. Although ultrasound can be used to detect adrenal abnormalities, it is not used as a primary imaging modality because of its inability to depict the entire adrenal gland in adults. In children, however, ultrasound is more commonly used to evaluate adrenal disease.

Since its introduction in the 1970s, CT has become the primary imaging tool for adrenal imaging because of its superior spatial resolution, its widespread availability, and the speed in which examinations can be performed. The advent of spiral CT, and more recently multidetector-row helical (spiral) CT, has allowed rapid thin-slice imaging through the adrenal glands during various phases of contrast enhancement.

The rapidity of CT has allowed the use of precontrast

Figure 40-2. Normal adrenal glands. Scans at six different levels (5-mm-thick slices) reveal variability in the size, shape, and configuration of the right (black arrows, arrowheads) and left (white arrows, arrowheads) glands at different levels in the same patient. For instance, the medial limb of the right gland extends superiorly (A–C). On the right (black arrows), both medial and lateral limbs are visible at only one level (D). The lateral limb extends inferiorly (black arrowheads in A and F). On the left, both limbs are visible on the upper three scans (white arrows and arrowheads in A–C). The lateral limb is visible only on the lower three scans (white arrows and arrowheads in D–F).

scans as well as post-intravenous (IV) contrast-enhanced scans to become routine. Oral contrast material can also be helpful in examination of the adrenal glands because unopacified (nonradiopaque) stomach or loops of bowel may be opacified so that adrenal “pseudomasses” can be clearly defined as bowel and not adrenal lesions. The use of oral contrast material is especially helpful after nephrec-

tomy, when loops of bowel may fall into the renal fossa and can make evaluation of the adrenal glands difficult.

In general, when CT is used to study the adrenal glands, the entire abdomen through the aortic bifurcation is scanned. The complete examination of the abdomen is helpful for staging or for evaluating possible ectopic adrenal lesions that may occur in certain disease processes.

In recent years, MRI has become the other primary imaging modality for identifying adrenal pathology. Initially, most adrenal lesions were evaluated with standard T1-weighted and T2-weighted, spin-echo images with magnets of low and medium field strength. With the advent of higher-field-strength magnets (1.5 tesla), chemical shift imaging and dynamic gadolinium-enhanced MRI have been added to the process of adrenal gland evaluation.

Chemical shift imaging is based on the fact that the resonant frequency of a given atom's nucleus is affected by its chemical environment. This is secondary to slight variations in local magnetic field strength caused by the shielding effects of nearby orbiting electrons. The change that occurs during an MR signal as a result of this effect is referred to as a chemical shift.

The chemical shift is used primarily to identify protons within the body that are located either within water molecules or within lipid molecules. This allows a separation of fat from water contributions in an image. Conventional spin-echo imaging results in water and lipid protons that are *in phase*; their magnetic moments are oriented in the same direction at the same time of the spin echo. When the imaging is *out of phase*, or *opposed*, signal detection occurs when lipid and water protons are oriented in opposite directions. The resulting image expresses the signal difference between water and lipid protons and therefore enables areas that are predominantly lipid to be distinguished from those that are predominantly water. This capability plays an important role in certain adrenal conditions, since certain adrenal lesions contain significant amounts of lipid.

The most common contrast agents used in MRI today involve gadolinium bound to diethylenetriamine-penta-acetic acid (DTPA). The physiologic characteristics of gadolinium agents are similar to those of iodinated contrast material. The distributions within the body and renal clearances are also similar, but the safety margin of gadolinium is greater than that of iodinated contrast material. The similarity to iodinated contrast material allows the principles of CT IV contrast enhancement to be extended to MRI. These techniques, along with the inherent strengths of MRI, which include the ability to obtain routine coronal and sagittal images and its superior contrast resolution compared with that of CT, have made MRI a mainstay in evaluating adrenal pathology.

Radionuclide imaging of the adrenal gland has been largely limited to the use of metaiodobenzylguanidine (MIBG) scans. MIBG is an analog of norepinephrine and is a useful agent for use in detecting functionary medullary tumors. β -Iodomethyl-19-norcholesterol (Np-59) has been used to detect glucocorticoid, mineralocorticoid, and androgen-secreting tumors. The advances made with both CT and MRI have largely eliminated the use of Np-59 imaging for adrenal imaging.

More recently, the increased availability of positron emission tomography (PET) has led to the development of several compounds as possible staging agents for tumors of the adrenal glands.⁴² The use of fluorodeoxyglucose (FDG)-PET for evaluating tumor metabolism in other sites of the body has been assessed. Malignant lesions demonstrate abnormally increased uptake of FDG. Whole body FDG-PET scanning allows detection of malignancies and

differentiation of malignant from benign masses, and this capability has been applied to the adrenal glands. FDG-PET scanning also has a role in staging extra-adrenal tumor sites.

Several inherent problems are associated with FDG-PET imaging:

1. Its lack of widespread availability.
2. The fact that pathologic lesions in the adrenal glands are often small and thus difficult to image.
3. Uptake in other abdominal structures, such as the renal pelvis, that can obscure the adrenal gland.

In past years, adrenal venous sampling was more commonly used to evaluate functioning adrenal tumors. It is now reserved for differentiating functioning adenoma from hyperplasia in patients with documented hyperaldosteronism; this is useful in aiding the endocrinologist and the surgeon to decide whether surgical treatment for hyperaldosteronism is indicated.

The general approach to imaging the adrenal glands has been the use of CT for screening and for depicting smaller lesions (3 cm or less) because of its superior spatial resolution. MRI is commonly used to further define lesions that have already been documented on CT scans or to evaluate larger adrenal lesions. Both CT and MRI play complementary roles in detection of most pathologic changes in the adrenal glands.

Functioning Adrenal Tumors

Conn's Syndrome

Primary hyperaldosteronism (Conn's syndrome) is a rare cause of hypertension, accounting for fewer than 1% of all cases of hypertension. It is a heterogeneous disease characterized by hypersecretion of aldosterone, moderate hypertension, and hypokalemia.⁵ In 70% of cases, this disease process is the result of an aldosterone-secreting adrenal adenoma. In this subsegment of cases, unilateral adrenalectomy is the treatment of choice.

These tumors are universally small, generally less than 2 cm in diameter (Fig. 40-3). There is a female predilection, with a peak incidence occurring within the fourth and fifth decades of life. On histologic evaluation, these aldosterone-secreting adenomas reveal primarily lipid-laden cells of the zona fasciculata. As a result, the lesions generally show low density on imaging studies (Figs. 40-4 and 40-5).

Most of the remainder (30%) of primary hyperaldosteronism are the result of adrenal hyperplasia, usually bilateral (Fig. 40-6), which is treated medically with pharmacologic agents.¹⁶ Histologic evaluation of patients with adrenal hyperplasia reveals hypertrophy of the zona fasciculata with underlying microscopic and macroscopic nodules. This results in the appearance of enlarged, irregular adrenal glands.

Rarer causes of primary hyperaldosteronism (<5% of all cases) include primary adrenal hyperplasia, renin-responsive aldosterone-secreting adenomas, and glucocorticoid-remediable aldosteronism.

The imaging approach to suspected primary hyperaldosteronism is to distinguish to the referring physician those

Figure 40-3. Aldosterone-producing adenoma. *A*, A tiny mass in the left adrenal gland (*black arrows*) preserves the configuration of the left adrenal gland but indents the central portion of the gland (*arrowheads*). *B*, Inspection of the gross specimen reveals both a tumor (*arrows*) and a portion of the normal glands (*arrowheads*).

Figure 40-4. Aldosterone-producing adenoma. A mass 1.5 cm in diameter in the right adrenal gland (*arrows*) is located posterior to, and is lower in density than, the inferior vena cava (*arrowheads*). *B*, Examination of the gross specimen revealed a high cholesterol content.

Figure 40-5. Aldosterone-producing adenoma. An adenoma 1 cm in diameter arises from the lateral limb of the right adrenal gland (arrow). The left adrenal gland (arrowhead) is normal.

patients with adrenal cortical adenomas as a cause of this disease process from patients with adrenal hyperplasia. The imaging modality of choice for evaluating patients with suspected primary hyperaldosteronism is CT because of its superior spatial resolution in depicting these small tumors.^{17, 22} The advent of helical CT and, more recently, multidetector-row helical CT has allowed one to routinely perform thin-slice imaging through the adrenal glands in a single breath-hold. Slices of the adrenal glands 2.5 mm thick or less can be obtained to evaluate aldosterone-secreting adenomas smaller than 2 cm in size. For these scans, IV contrast material is not required.

The lesions seen in hyperaldosteronism secondary to a solitary adenoma generally appear as a low-density oval mass under 2 cm in size and frequently eccentric within the gland.^{26, 32} Blood samples from each adrenal vein can be assayed for elevated aldosterone levels. This test is confirmatory but is not done in all cases because of its invasive nature.

Primary hyperaldosteronism secondary to adrenal hyperplasia generally results in adrenal glands that are mildly enlarged and have an irregular surface because of the presence of underlying microscopic and macroscopic nodules.^{16, 17} Usually, no single dominant nodule can be seen with the adrenal glands. Up to one third of these patients,

Figure 40-6. A-C, Conn's syndrome. Thin-section CT imaging of the adrenal glands reveals multinodular hyperplasia of both adrenal glands, resulting in primary hyperaldosteronism (Conn's syndrome) in this patient.

however, have normal-appearing adrenal glands on imaging studies.⁶⁰ When a patient with suspected primary hyperaldosteronism has either normal-appearing adrenal glands or glands that are mildly enlarged with multiple nodules, adrenal venous sampling is performed to aid in the diagnosis and localization of the disease process.

Cushing's Syndrome

Cushing's syndrome is a well-documented disease of chronic excess of circulating glucocorticoids.^{25, 70} The clinical features, which appear in varying degrees of severity, include obesity, plethora, bruising, abdominal striae, and muscle wasting. Frequently, osteoporosis and delayed wound healing are also present. As a result of the effects of glucocorticoids on glucose metabolism, 10% to 15% of the patients have diabetes mellitus.

The causes of Cushing's syndrome are many. In 70% of cases, the cause is pituitary disease secondary to an adrenocorticotrophic hormone (ACTH [corticotropin])–secreting adenoma.⁷² Five percent of cases result from ectopic ACTH secretion; this usually occurs in certain types of malignancy, including lung carcinomas, islet cell tumors, and ovarian neoplasms.

In 20% of cases, Cushing's syndrome is secondary to an adrenal adenoma. These adenomas are larger than those seen in Conn's syndrome, usually 2 to 4 cm in size. They contain a large amount of lipid-laden cells, giving them a characteristic low-density appearance on CT scans (Fig. 40–7).^{48, 49}

The final major etiologic mechanism in approximately 5% of cases of Cushing's syndrome is adrenal cortical carcinoma. These generally large tumors occupy much of the right or left upper quadrant, depending on the adrenal

gland involved. Frequently there is associated necrosis and hemorrhage. Only 10% of adrenal cortical carcinomas function to a level that results in Cushing's syndrome.

The initial imaging of the adrenal glands is usually performed with CT because of its superior spatial resolution and the ability to perform routine thin-slice imaging. The imaging process is facilitated by the large amount of retroperitoneal fat that is usually present in patients with Cushing's syndrome. The low-density imaging appearance of these 2- to 4-cm adenomas is the result of the large amount of lipid in the cytoplasm of their cells (Fig. 40–8).

It is vital that the radiologist observe the thickness of the unaffected limbs of the adrenal gland when evaluating a patient with an adrenal nodule for Cushing's syndrome.¹⁰ Cortisol-producing adenomas suppress ACTH levels, resulting in atrophy of the remaining adrenal tissue. If normal adrenal thickness is observed, the adrenal lesion is not responsible for Cushing's syndrome.

Adrenal gland hyperplasia secondary to pituitary or ectopic causes of Cushing's syndrome can have several imaging appearances (e.g., normal-appearing glands, bilateral uniform adrenal enlargement, adrenal glands with irregular small nodules on the surface, or a multinodular gland with larger dominant nodules).²⁹ The most common pattern of adrenal hyperplasia is diffuse bilateral enlargement without a focal mass (Fig. 40–9). In some cases of Cushing's syndrome secondary to hyperplasia, when evaluation of the pituitary gland does not reveal an adenoma, petrosal venous sampling may be valuable in determining the cause.

MRI has played a secondary role in the evaluation of patients with Cushing's syndrome because CT can better evaluate the smaller adrenal masses. MRI signal intensity seen in adrenal hyperplasia closely follows that of the normal adrenal gland, rendering MRI less sensitive than CT in evaluating adrenal hyperplasia.

Figure 40–7. Right adrenal gland adenoma in a patient with Cushing's disease. A, A tumor 2 cm in diameter in the right adrenal gland (black arrow) is associated with a hypoplastic ipsilateral remnant (arrowheads). The left gland is also hypoplastic (white arrow). B, The gross specimen includes the hypoplastic remnant (arrowheads).

Figure 40-8. Left adrenal gland adenoma in a patient with Cushing's disease. *A*, A mass 2.5 cm in diameter can be seen in the left adrenal gland (large white arrow). Also visible is a hypoplastic remnant of the left adrenal gland (arrowhead). The right adrenal gland (small white arrow) is hypoplastic. *B*, The gross specimen includes the hypoplastic remnant (arrowheads).

Cushing's syndrome. *A-C*, Non-contrast-enhanced and contrast-enhanced CT scans of the adrenal glands reveal symmetrical hypertrophy. *D*, CT scan of the chest demonstrates a 1-cm nodule in the right middle lung. The nodule was a bronchial carcinoid ectopically secreting adrenocorticotrophic hormone, which resulted in Cushing's syndrome. (Courtesy of Mayo Foundation.)

Adrenogenital Syndrome

Adrenogenital syndrome is characterized by excessive secretion of sex hormones and causes virilization, feminization, or precocious puberty, depending on the hormones secreted and the age of the patient.²⁻⁴ Androgen excess is

the most common form of this syndrome; of the cases diagnosed clinically, 80% occur in female patients. In prepubertal girls, the consequences are clitoral hypertrophy, development of male secondary sex characteristics, and early closure of bony epiphyses. In prepubertal boys, changes include precocious puberty. In adults, men usually

Figure 40-10. Pheochromocytoma. *A* and *B*, Non-contrast-enhanced (*A*) and contrast-enhanced (*B*) CT scans reveal a solid left adrenal mass, 4 cm in diameter. *C–E*, Whole body imaging using metaiodobenzylguanidine (MIBG) (*C*) and SPECT imaging of the pelvis (*D* and *E*) show intense uptake in the left adrenal mass. This 4-cm pheochromocytoma was successfully resected. (Courtesy of Mayo Foundation.)

undergo testicular atrophy secondary to pituitary suppression, whereas women undergo changes including amenorrhea, hirsutism, and virilization. Less commonly, the presence of estrogen-secreting tumors results in precocious puberty in girls and feminization in males.

Adrenogenital syndrome is most often caused by congenital adrenal hyperplasia secondary to an enzymatic deficiency in adrenal steroid synthesis, resulting in an overproduction of androgens. Approximately 25% of patients have associated overproduction of mineralocorticoids as well. The imaging findings in patients with congenital adrenal hyperplasia are generally those of uniformly enlarged adrenal glands.

Both benign adrenal adenomas and adrenal cortical carcinomas can give rise to adrenogenital syndrome. These lesions have the imaging characteristics of both tumors. In general, in adults a higher proportion of malignant adrenal cortical tumors results in adrenogenital syndrome than in benign lesions.

Pheochromocytoma

Pheochromocytoma is a rare tumor of the chromaffin cells of the adrenal medulla; it affects approximately 1 in 200,000 individuals in the general population.^{12, 78} The biochemical diagnosis is facilitated by characteristic symptoms and signs attributable to excessive release of catecholamines. Pheochromocytomas usually secrete both epinephrine and norepinephrine. The characteristic clinical findings include severe headaches, palpitations, excessive sweating, tremor, anxiety, and sustained hypertension.

Pheochromocytomas are extra-adrenal in 10% of cases, multicentric in 10%, bilateral in 5%, and malignant in 10%. They are relatively large (~5 cm in size), but sizes range from 1 cm to above 20 cm. Smaller tumors may be seen when bilateral pheochromocytomas are present or in patients with multiple endocrine neoplasia (MEN).

Pheochromocytomas are associated with MEN types 2A and 2B, von Hippel-Lindau disease, neurofibromatosis, Sturge-Weber syndrome, and Carney's triad. They are gen-

erally well-defined adrenal lesions with occasional areas of necrosis or cystic changes. Treatment is surgical excision of the tumor, which is curative in almost all cases.

The initial imaging findings in benign and malignant pheochromocytomas are nearly identical. Only the presence of metastasis can clearly define a pheochromocytoma as malignant.

Imaging is performed to localize a tumor that has already been diagnosed biochemically. Urinary or serum catecholamine levels are measured to confirm the diagnosis. The radiologist's role is to identify whether the pheochromocytoma is intra-adrenal and whether it is unilateral or bilateral.⁷⁸

Ectopic pheochromocytomas can occur anywhere neural crest cells are present in the body. Tumors have been reported from the base of the brain to the epididymis, making preoperative localization imperative. The most common extra-adrenal site of pheochromocytoma is the organ of Zuckerkandl at the aortic bifurcation.

CT has long been the primary method of diagnosis. On scans, intra-adrenal pheochromocytomas appear as round or oval, discrete masses whose density is homogeneous (Fig. 40-10).⁷⁸ Central necrosis, calcification, and cystic changes may be present in a minority of cases (Fig. 40-11).²⁰ These vascular lesions enhance uniformly after administration of contrast material. The use of IV iodinated contrast material in patients with pheochromocytoma has been controversial because it may cause a hypertensive crisis; however, the use of low-osmolality iodinated contrast material has largely eliminated that concern. The incidence of elevated circulating serum catecholamines with low-osmolality contrast material is generally negligible.⁴⁷

In patients with suspected adrenal pheochromocytoma, CT scans of the entire abdomen through the aortic bifurcation are generally obtained to identify possible ectopic tumor (Fig. 40-12). Helical scanning done at 5-mm increments with IV contrast material is the preferred technique. The accuracy of CT in detecting intra-adrenal pheochromocytomas is nearly 100%.⁷⁸

MRI is also excellent for evaluating intra-adrenal pheochromocytomas.^{11, 34, 37, 39} Because these are generally larger

Figure 40-12. Pheochromocytoma. A, Whole-body metaiodobenzylguanidine (MIBG) scan demonstrates uptake in the lower abdomen and upper pelvis. B–D, Contrast-enhanced CT scans of the abdomen and pelvis demonstrate normal-appearing adrenal glands; multiple cysts are present in the liver. A solid, 3-cm enhancing mass at the aortic bifurcation is compatible with a pheochromocytoma in the organ of Zuckerkandl. This tumor was successfully resected. (Courtesy of Mayo Foundation.)

tumors (5 cm), the poorer spatial resolution of MRI is usually not a problem. On T1-weighted images, pheochromocytomas have a signal intensity similar to or slightly lower than that of other solid organs of the abdomen. On T2-weighted images, they tend to have a hyperintense signal as a result of their long T2 times (Fig. 40-13).^{11, 34, 37, 63} Although this finding is almost uniformly seen with pheochromocytomas, a percentage of adrenal metastases have overlapping imaging findings.

MIBG scanning can play a complementary role in evaluating intra-adrenal pheochromocytomas. The combination of an adrenal mass seen on a CT scan or an MR image and uptake on MIBG scanning is definitive in the diagnosis of pheochromocytoma. This approach is limited by the lack of availability of MIBG scanning equipment in some settings.

The imaging of extra-adrenal and recurrent pheochromocytomas is more complex, and MIBG scintigraphy is extremely valuable in these situations. MIBG is a precursor of catecholamines and therefore is actively taken up in

catecholamine-producing tissues. After recurrent, metastatic, or extra-adrenal lesions are initially discovered via whole body MIBG scanning, CT or MRI can then be performed for more accurate anatomic localization of the lesion to be resected (Fig. 40-14).

Adrenal Hypofunction

Hypofunction of the adrenal gland primarily refers to disorders of the adrenal cortex. Currently, no syndromes of adrenal medullary hypofunction are known. Initial work on hypofunctioning adrenal cortex was pioneered by Thomas Addison.¹ Hypofunction of the adrenal cortex may result either from its destruction (secondary to many disease processes) or from inadequate stimulation of the adrenal by the pituitary gland. These are classified as *primary* and *secondary* hypofunction, respectively.

Hypoadrenocorticism is a diagnosis that is often overlooked or delayed in many patients. The symptoms of

Figure 40-13. Pheochromocytoma. *A* and *B*, MR scans of a 3.5-cm solid right intra-adrenal pheochromocytoma. On T2-weighted images, this tumor demonstrates the hyperintense signal intensity commonly seen in intra-adrenal pheochromocytomas.

lethargy, fatigue, and weakness are uniform among these patients, but may be confused with other clinical entities. Weight loss, anorexia, abdominal pain, and hypotension are further clinical signs and symptoms of hypoadrenalism.

Potential causes of primary adrenal cortical failure include^{53, 81-84}:

- Autoimmune disorders
- Infection (most commonly, fungal infections and tuberculosis)
- Drugs that inhibit cortical synthesis
- Drugs that increase cortical clearance
- Hemorrhage
- Metastasis
- Sarcoidosis
- Hemochromatosis
- Amyloidosis

The most common drug that inhibits cortisol synthesis is ketoconazole; drugs that increase cortisol clearance and result in this syndrome include barbiturates and phenytoin (Dilantin). Hypocortisolism occurs with equal frequency in adults of both genders.

The role of imaging in the diagnosis of primary adrenal hypofunction is to evaluate the causes of primary adrenal failure. In patients with an autoimmune disease and primary adrenal cortical failure, the adrenal glands are uniformly small. When infection is the primary cause, the glands may be acutely enlarged or, in the case of chronic infection, may contain areas of calcification.

On a CT scan, hemorrhage caused by septicemia or anticoagulant therapy is seen as a characteristic high-density mass or infiltrating process in one or both adrenal glands. The high-density material follows the normal pattern of blood on CT scanning; the density diminishes over

Figure 40-14. Recurrent pheochromocytoma. CT was performed to evaluate the left adrenal gland in a patient with biochemical evidence of a recurrent pheochromocytoma. The original tumor had been removed several years previously. *A*, CT scan at one level shows normal left adrenal gland (white arrow) but also reveals a low-density mass, 1.5 cm in diameter, in the operative site (black arrows). *B*, CT scan at a slightly higher level shows two additional nodules (arrows) between the right lobe of the liver and the diaphragm. At surgery, these were found to be three nodules of pheochromocytoma "rests."

the next several weeks.^{30, 31} When metastases are the cause of primary adrenal cortical failure, the adrenal gland shows the characteristic appearance of the metastases.

Usually, 85% to 90% of the adrenal cortex must be destroyed before adrenal hypofunction is classified as a clinically relevant syndrome. Thus, adrenal hypofunction occurs in a minority of such patients because these disease processes often do not destroy enough adrenal cortex to result in hypofunction.

Nonfunctioning Adrenal Gland Disease Processes

Adrenal Cortical Adenomas

Adrenal cortical adenomas are common benign tumors found in 3% of autopsies and in 1% of all patients undergoing abdominal CT.⁴⁶ Benign nonfunctioning adenomas are asymptomatic and usually discovered incidentally in an imaging study.¹⁸ Histologically, they are composed of an admixture of clear, lipid-rich cells arranged in small cords.²⁴ The cause is thought to be overgrowth of adrenal cortical cells in response to previous injury or vascular insult. Nonfunctioning adenomas appear to increase with age and hypertension. Nonfunctioning adrenal adenomas tend to be small (usually less than 3 cm), sharply marginated, homogeneous masses.

CT often demonstrates a sharply marginated, rounded, homogeneous mass that shows low density.^{27, 30, 32} The use of nonenhanced CT for characterization of benign adrenal masses relies on the fact that adrenal adenomas contain a large number of lipid-rich cells, often resulting in Hounsfield unit (HU) values near or below zero (Figs. 40-15 and 40-16).

The literature contains reports of more than 500 adrenal lesions that have been analyzed on unenhanced CT scans.^{7, 20, 30, 35, 38, 44, 45, 68} These series present data for different manufacturers and slice thicknesses. In general, the unenhanced scans of adrenal lesions with attenuation val-

ues of 18 HU or less exhibit a sensitivity of 86% and a specificity of 88% in identifying benign adrenal adenomas. As the HU value falls toward zero, the specificity increases, reaching 100% at 2 HU. To obtain the HU value in the region of interest, at least half of the cross-sectional area of the lesion should be included on the selected CT slice.

Much attention has been focused on the use of delayed contrast-enhanced CT to differentiate benign adrenal adenomas from nonadenomas. Reports were based on the demonstration that adrenal adenomas had significantly lower attenuation than that of nonadenomas on delayed contrast-enhanced CT scans at arbitrarily chosen times (between 3 and 50 minutes) after contrast infusion.^{36, 75} In several studies, attenuation thresholds of 24 HU or less after contrast administration indicated that the lesions were benign.^{6, 74} Results varied according to the volume and type of contrast material infused, how it was infused, and the type of scanner used.

The washout of contrast material at the delayed times was assessed in several studies involving contrast-enhanced CT. The results showed that adenomas enhanced significantly more than nonadenomas did at 30, 60, and 90 seconds after contrast infusion. When scans were delayed as long as 30 minutes after contrast infusion, the loss of contrast enhancement and the relative percentage of loss of contrast enhancement were significantly greater for adenomas than for nonadenomas.

Two methods of evaluating contrast washout are used. The patient is scanned without contrast material, then again at 70 seconds, and then 15 minutes after IV contrast administration. The percent enhancement washout is calculated by the formula

$$\frac{E - D}{E - U} \times 100$$

where

E is the 70-second IV postcontrast enhancement value

D is the 15-minute IV postcontrast enhancement value

U is the unenhanced value

Figure 40-15. Adenoma. A and B, Non-contrast-enhanced CT scans demonstrate a 1.5-cm low-density mass in the right adrenal gland. The mass measured -24 Hounsfield units (HU), indicating that this is a benign adenoma.

Figure 40-16. Adenoma. *A* and *B*, Nonenhanced CT scans demonstrate a 2-cm low-density right adrenal mass. The attenuation value for the region of interest in this mass was -10 Hounsfield units (HU), indicating that this was a benign adenoma. *C* and *D*, Non-contrast-enhanced CT scans at a slightly lower level in the same patient demonstrated a solid-appearing, 2-cm right adrenal mass. The region of interest in this mass measured 20 HU, which did not clarify whether it was benign or malignant. *E*, Percutaneous biopsy of the solid mass via a transhepatic approach revealed a benign adenoma. Incidentally noted was a 9-mm benign adenoma in the opposite adrenal gland.

All values are in HU.

If percent enhancement washout is greater than 60%, the lesion is benign.

If no enhanced values are available, the relative washout can be used. The formula for relative washout is

$$\frac{E - D}{E} \times 100$$

If the value is greater than 40%, the lesion is benign.^{33a}

MRI has been used to distinguish benign adenomas from nonadenomas. Initial reports using low-field-strength magnets and comparing the density of the adrenal lesion to that of other solid abdominal organs showed initial promise, but there was significant overlap with nonadenomas.^{24, 43, 55, 63, 66, 67} This technique has not been regarded as useful for evaluating benign adrenal adenomas.

The technique of chemical shift imaging to detect lipid within an adrenal mass has become one of the most common techniques of evaluating adrenal adenomas (Fig. 40-17).⁶⁷⁻⁶⁹ Because most adrenal adenomas contain lipids but nonadenomas do not, chemical shift imaging readily reveals adrenal masses as adenomas when they lose signal and appear dark on opposed-phase images compared with their appearance on in-phase images.

More recently, the use of dynamic gadolinium-enhanced MRI has also been successfully applied to differentiate benign adrenal adenomas from nonadenomas.^{39, 68} With this technique, imaging is usually performed through the adrenal lesion at 20- to 30-second intervals starting with the infusion of the initial bolus of gadolinium and continuing for 5 minutes. Generally, gadolinium in a dose of 1.1 mmol/kg of body weight is used. The principles of gadolinium-enhanced studies are similar to those of contrast-enhanced CT studies. Adenomas show moderate enhancement initially, with quick washout, whereas malignant tumors and other benign tumors, such as pheochromocytomas, show stronger overall contrast enhancement with

slower washout. The overall specificities and sensitivities of chemical shift and gadolinium-enhanced MRI for differentiating adrenal adenomas from nonadenomas range from 81% to 100% and from 80% to 100%, respectively.

Both unenhanced CT and delayed contrast-enhanced CT as well as MRI using chemical shift or dynamic gadolinium-enhanced techniques are accurate for differentiating most adrenal adenomas from nonadenomas. The diagnosis is based on the presence of lipid within these lesions or the characteristic enhancement pattern of adenomas versus nonadenomas. Unfortunately, a significant number of adenomas, as many as 10%, do not have a high-enough lipid content or do not behave characteristically in contrast enhancement, rendering the techniques ineffective.⁵⁰ In such cases, patients can be monitored at 6-month intervals for changes in the adrenal lesion, or they can undergo percutaneous biopsy.

Adrenal "Incidentalomas" (Incidentally Discovered Adrenal Lesions)

The workup of clinically silent and incidentally discovered adrenal lesions can present a challenge. Increasingly, CT and MRI techniques have helped in their evaluation.

The size of an adrenal lesion is important in predicting its behavior.⁴⁵ Benign adrenal lesions generally grow slowly; 87% of adrenal masses smaller than 3 cm in diameter are benign, whereas 95% of masses larger than 3 cm are malignant. Lesions greater than 6 cm in diameter are almost always malignant.⁵⁶ In most cases, lesions this large should undergo biopsy or should be treated without further diagnostic study.

The most practical and cost-effective way to evaluate nonfunctioning, incidentally discovered adrenal lesions is to use the imaging modality by which they were discovered. For example, if a lesion is discovered on a CT scan, unenhanced or delayed-contrast imaging can be performed

Figure 40-17. Adenoma. A and B, MR images of a 2.5-cm left adrenal mass. Loss of signal on opposed-phase chemical shift imaging showed that this lesion was a benign adenoma.

Figure 40-18. Algorithm for evaluating an incidentally discovered adrenal lesion.

at that time to further characterize it. If the lesion is discovered via MRI, chemical shift imaging or dynamic gadolinium enhancement can be performed.

Note that there are no imaging criteria that clearly distinguish benign nonfunctioning adenomas from benign functioning adenomas other than the clinical presentation. Figure 40-18 presents a suggested workup of the incidentally discovered adrenal lesion, summarized as follows:

1. Use clinical and laboratory analyses to decide whether the tumor is functioning. If the tumor is functioning, recommend medical or surgical therapy.
2. If the tumor is nonfunctioning, perform CT, MRI, or both to determine whether it is benign. If the tumor is shown to be benign, stop the workup.
3. If the lesion does not have the characteristics of a benign lesion, determine its size.
4. If the lesion is smaller than 5 cm, follow up at an interval of 6 months.
5. If the patient has an underlying malignancy, however, and the lesion is smaller than 5 cm, recommend biopsy.
6. If the lesion is larger than 5 cm and does not have benign characteristics, recommend percutaneous biopsy or surgery.

Recent data suggest that 5% to 25% of patients with adrenal incidentalomas have some form of subclinical hormonal dysfunction and may represent a population at higher risk for metabolic and cardiovascular disease. The adrenal incidentaloma will continue to be an evolving subject of research and clinical evaluation in the future.^{47a}

Adrenal Cortical Carcinomas

Adrenal cortical carcinomas are unusual neoplasms, occurring in less than 0.1% of the population. These tumors

affect women more frequently than men, with a bimodal age distribution consisting of an initial peak in the first two decades of life and a second peak in the fifth and sixth decades.²

Ten percent of these tumors are clinically functional. When functional, they usually coexist with Cushing's syndrome or a mixed endocrine manifestation.⁹ The patient usually presents with a large abdominal mass and experiences symptoms of abdominal pain and weight loss. At the time of presentation, these tumors are often larger than 10 cm in size and are invasive. By the time of diagnosis, they are either locally invasive or metastatic in nearly 90% of patients.^{9, 77}

Determining malignancy can be difficult because of the subtle differences between benign and malignant cortical tumors. Adrenal cortical carcinomas can especially be difficult to differentiate from those benign adrenal adenomas that tend to be large (>5 cm in size) and contain large areas of degeneration, hemorrhage, calcification, and necrosis.⁵⁰

The radiologic findings show a large mass that usually envelops much of the area surrounding the involved adrenal gland.^{20, 39, 44} Most such masses show degenerative and cystic changes, and 33% contain calcifications. CT and MRI findings reflect the pathologic changes that occur within these large, frequently necrotic, and sometimes calcified tumors. Contrast-enhanced CT shows them to be relatively vascular in certain areas. With MRI, the masses show low signal intensity on T1-weighted images and higher signal intensity on T2-weighted images when compared with the liver. Signal intensity generally increases on opposed-phase chemical shift imaging.

When CT or MRI is performed, the tumors should be staged. They tend to be locally invasive, especially in vascular structures such as the adrenal vein, the renal vein, and the inferior vena cava (Fig. 40-19). In case reports,³⁴ smaller adrenal cortical carcinomas have showed decreased signal intensity on opposed-phase chemical shift imaging compared with in-phase imaging, but this should not dissuade the radiologist from looking for the other signs of malignancy usually associated with these tumors.

Treatment of adrenal cortical carcinomas consists of surgical resection.

Adrenal Metastases

At autopsy, metastases to the adrenal glands are found in up to 27% of patients dying of cancer. Certain tumors are more likely than others to metastasize to the adrenal glands.^{41, 52, 65} Of breast and lung carcinomas that are metastatic, 30% to 40% have adrenal metastases. Of melanomas, 50% show metastatic lesions to the adrenal glands. Less common causes of adrenal metastasis include gastrointestinal tumors and renal cell carcinoma.

Metastases generally involve the boundary between the cortex and the medulla, but spread to either part of the organ occurs. Metastases are usually asymptomatic, but in rare cases hypoadrenalism can occur. Because of the incidence of benign adrenal adenomas in patients with documented underlying malignancies, 50% of all adrenal lesions in patients with malignancies still represent benign adrenal adenomas.

Figure 40-19. Adrenal cortical carcinoma. *A* and *B*, Contrast-enhanced CT scans of the abdomen demonstrate a large heterogeneous right adrenal mass invading the inferior vena cava. *C-F*, MR images demonstrate a large right adrenal cortical carcinoma with invasion of the inferior vena cava.

The CT findings of metastatic disease to the adrenal gland demonstrate that metastases tend to be larger and less well defined, with inhomogeneous central areas that have thick, irregularly enhancing rims. The metastases are frequently bilateral (Fig. 40-20).^{20, 32, 37}

Metastases usually demonstrate an attenuation of more

than 20 HU on unenhanced CT scans. On delayed contrast-enhanced CT, the value is generally higher and the metastases tend to remain enhanced longer than adrenal adenomas; at 30 minutes, metastases show an attenuation of more than 40 HU.

MRI has been used to differentiate metastatic disease

Figure 40-20. Adrenal metastasis. A and B, Contrast-enhanced CT scans of the abdomen reveal a 4.5-cm left adrenal mass that is inhomogeneous and irregular. The patient had an underlying lung carcinoma; percutaneous biopsy indicated left adrenal metastasis.

from benign adrenal tumors. Initially, T1-weighted and T2-weighted signal intensities were studied in other organs in an attempt to differentiate metastases from adenomas. Unfortunately, because of signal intensity overlap in 20% to 30% of cases, these methods were not useful.

Next, dynamic gadolinium-enhanced MRI and chemical shift imaging were studied for their ability to evaluate adrenal masses. Chemical shift imaging demonstrated that it is rare for nonadenomatous lesions to have a loss of signal intensity on opposed-phase images compared with in-phase images. On dynamic gadolinium-enhanced scans, lesions that had marked enhancement on delayed series were more likely to be malignant. In a small percentage of lesions, these imaging findings overlapped, showing appearances characteristic of both adenomas (particularly large degenerating ones) and metastases. When neither CT nor MRI is sufficient to determine whether an adrenal mass is benign or malignant, a patient with a suspected or diagnosed malignancy should undergo percutaneous adrenal biopsy to allow histopathologic examination.

Adrenal Hemorrhage

Adrenal hemorrhage and infarction can have multiple causes, both *traumatic* and *nontraumatic*.³¹ In the case of trauma, adrenal hemorrhage is usually unilateral to the side of the trauma. For example, in a patient who has undergone liver transplantation, unilateral right adrenal gland hemorrhage and infarction tend to occur after ligation and division of the right adrenal vein.⁸

Nontraumatic causes include physiologic stress, usually secondary to surgery or sepsis.⁵¹ Other causes include a bleeding diathesis, an underlying adrenal tumor, and certain idiopathic conditions.^{58, 71} The clinical manifestations of nontraumatic adrenal hemorrhage depend on (1) the amount of hemorrhage and its rate of onset, (2) the presence or absence of hemorrhage into the perinephric space, and (3) the patient's underlying hematologic status.

Patients may be asymptomatic or may present with

sudden or gradual onset of upper abdominal flank or back pain. If the hemorrhage is massive, signs and symptoms of blood loss can occur.

It is unusual for adrenal insufficiency to result from adrenal hemorrhage, but when this occurs, it can be life-threatening because the patient is often under other critical physiologic stresses. Generally, more than 90% of the adrenal gland must be destroyed before insufficiency occurs.⁸³

The unique blood supply of the adrenal gland results in a predisposition to adrenal hemorrhage. The vascular system of the adrenal gland is termed a *vascular dam*.¹⁵ The system consists of multiple small arterial branches that form a subcapsular plexus, and there are few draining venules. With physiologic stress, the vascularity of the adrenal gland increases, venous pressure becomes elevated, and venous constriction can occur. As a result, this intrinsically vulnerable network is susceptible to hemorrhage.

Imaging findings of acute adrenal hemorrhage are usually discovered incidentally. On CT scans, the adrenal glands appear as round or oval masses that may have stranding if hemorrhage into the perirenal fat is present. Acute to subacute hemorrhages contain areas of high attenuation, usually between 50 and 90 HU on nonenhanced CT scans (Fig. 40-21). Adrenal hematomas generally regress over time and almost always resolve completely. Calcification can occur but usually not within the first year after hemorrhage. If a hematoma organizes and becomes relatively cystic, it is called an *adrenal pseudocyst*.

In the *acute* stage, adrenal hematomas displayed by MRI generally demonstrate isointense or slightly hypointense signal on T1-weighted images and markedly hypointense signal on T2-weighted images. The findings on T2-weighted images are caused by a high concentration of intracellular deoxyhemoglobin, which leads to the T2 proton relaxation characteristics.

In the *subacute* stage, about 7 to 10 days after the initial hemorrhage, the hematoma appears hyperintense on both T1-weighted and T2-weighted images. The T1 shortening that occurs during this time is caused by the paramagnetic

Figure 40-21. Adrenal masses. *A*, Contrast-enhanced CT scan of the abdomen indicates bilateral adrenal masses that contain high-density material compatible with adrenal hemorrhage. *B*, Follow-up scan performed 7 months later reveals regression of the bilateral adrenal masses, which is compatible with resolution of adrenal hemorrhage.

effect of free methemoglobin, which is produced as the hematoma ages.

In the *chronic* stage, usually 2 to 3 months after the hemorrhage, a hypointense rim can be seen on both T1-weighted and T2-weighted images. Gradient-echo imaging is helpful to demonstrate the “blooming,” or magnetic susceptibility effect, that results from hemosiderin deposition at this stage. Appreciating adrenal hemorrhage is important in the management of patients who have undergone significant injury or physiologic stress.

Myelolipomas

Myelolipomas are benign and relatively uncommon adrenal tumors. They contain a variable mixture of fat and hemopoietic elements that frequently resemble bone marrow.^{14, 24, 33, 62} Myelolipomas almost always occur within the adrenal gland but have been reported in other locations in the retroperitoneum. Most of these lesions are asymptomatic and are found on routine imaging for other reasons.

Occasionally, acute hemorrhage occurs within these lesions, or certain functional conditions such as Cushing's syndrome or Conn's syndrome can occur. When myelolipomas undergo acute hemorrhage, patients usually present with a sudden onset of pain, hypotension, and documented blood loss. Myelolipomas that spontaneously hemorrhage are usually larger than 10 cm in size. No malignant potential is associated with these lesions.

The hallmark of imaging these tumors by CT, ultra-

Figure 40-22. Adrenal myelolipoma. Contrast-enhanced CT scan of the abdomen demonstrates a 3.5-cm left adrenal mass containing a large amount of fat. This mass is characteristic of an adrenal myelolipoma.

sound, or MRI is identification of the areas of fat within the lesion (Fig. 40-22). On CT scans, layers of fat are usually interspersed with areas of high-attenuation tissue (Fig. 40-23). Ultrasound shows myelolipomas as generally hyperechoic masses, with the more hypoechoic regions representing the myeloid components.

On MR images, the predominantly fatty areas demonstrate increased signal intensity on T1-weighted images. The appearance on T2-weighted images is more complex because of the admixture of marrow and soft tissue elements within the fat. Chemical shift opposed-phase imaging, also used for identifying benign adrenal adenomas, should demonstrate low signal intensity in areas that contain fat.

Management generally involves observation unless the tumor is functioning or acute hemorrhage occurs.

Figure 40-23. Myelolipoma. Contrast-enhanced CT scan of the abdomen reveals a 6-cm by 7-cm right adrenal mass containing both fat and soft tissue elements. This appearance is compatible with a myelolipoma.

Figure 40-24. Lymphoma. *A* and *B*, Contrast-enhanced CT scans of the abdomen demonstrate bilateral infiltrating soft tissue masses within both adrenal glands. The appearance is compatible with that of a lymphoma. Involvement of the liver can be seen on the lower-level scan of the series. The patient underwent percutaneous adrenal biopsy, which resulted in a diagnosis of non-Hodgkin's lymphoma.

Lymphoma

Adrenal glands are an unusual site for primary lymphoma. At autopsy, however, the adrenal gland has been found to be involved in up to 25% of patients with disseminated non-Hodgkin's lymphoma. In all age groups, involvement of the adrenal glands occurs more often in patients with non-Hodgkin's lymphoma than in those with Hodgkin's disease. Involvement is bilateral in 70% of cases (Fig. 40-24). Although lymphoma of the adrenal glands may present as a solid mass or as solid masses, the most common presentation is of diffuse bilateral enlargement of the adrenal glands (Fig. 40-25).

Generally, treatment of lymphoma in the adrenal glands is similar to that of other sites.²¹

Figure 40-25. Non-Hodgkin's lymphoma. Contrast-enhanced CT scan of the abdomen demonstrates solid bilateral adrenal masses. Biopsy revealed the diagnosis.

Miscellaneous Adrenal Conditions

Cysts

Adrenal cysts are rare lesions that are usually found incidentally at imaging or autopsy. The cysts are endothelial in 45% of cases, pseudocysts in approximately 40%, epithelial in 10%, and parasitic in 5%.^{19,28} Endothelial cysts are most often lymphangiomatous and contain clear fluid (Fig. 40-26). Pseudocysts usually result from previous adrenal injury or hemorrhage and contain fibrinous walls with no obvious lining (Fig. 40-27). Epithelial cysts are usually degenerated benign neoplasms or embryonal cysts. Parasitic cysts are usually secondary to echinococcal infections.

Figure 40-26. Adrenal and renal cysts. Oval, low-density mass with a thin wall can be seen in the left adrenal gland (*arrow*). The density of the left adrenal cyst is slightly greater than that of the cyst in the upper pole of the right kidney (*curved arrow*), but the attenuation value is compatible with a diagnosis of a cyst.

Figure 40-27. Adrenal pseudocysts. *A* and *B*, Contrast-enhanced CT scans of two patients reveal nodular calcification in right adrenal cystic lesions. These lesions, which remained stable over several years, were thought to represent adrenal pseudocysts resulting from previous trauma.

Imaging findings are similar to those of simple cysts found elsewhere in the body. Pseudocysts or echinococcal cysts appear as more complex cystic masses that can be difficult to differentiate from cystic neoplasms.⁶⁴

Infection

Infection in the adrenal glands is most commonly fungal or tubercular.⁸⁰⁻⁸² Adrenal gland involvement is often bilateral and in the acute setting results in diffuse enlargement of the adrenal glands (Fig. 40-28). Patients with underlying immune compromise, including those with acquired immunodeficiency syndrome (AIDS), are more susceptible to

Mycobacterium avium-intracellulare infection.²³ The adrenal glands may appear normal on imaging studies. In the chronic stage of infection, a calcified mass or diffuse adrenal calcification can be seen.

Solid Lesions

Several solid lesions that involve the adrenal glands are extremely rare⁵⁴:

- Adrenal hemangiomas
- Ganglioneuromas
- Adrenal angiosarcomas
- Primary malignant melanomas

Figure 40-28. Tuberculous infection. *A* and *B*, Contrast-enhanced CT scans show infiltrating soft tissue masses shaped like adrenal glands. Percutaneous biopsy indicated acute tuberculous infection of the adrenal glands in an immunocompromised patient.

Adrenal Hemangiomas

Adrenal hemangiomas are generally asymptomatic and usually involve the adrenal cortex. Calcifications are common, and on contrast-enhanced CT scans peripheral nodular enhancement is seen. Complete enhancement is unusual because of inner necrosis and fibrosis. MRI findings usually consist of high signal intensity on T2-weighted images, with central areas of decreased signal intensity resulting from fibrotic scar.

Ganglioneuromas

Ganglioneuromas are rare, benign neoplasms that originate from sympathetic ganglia.⁶¹ Most patients are older than 40 years of age and have no symptoms. The tumors present as well-defined, oval, discrete masses. With contrast enhancement, delayed heterogeneous uptake of contrast material results in incomplete filling of the tumor. On T1-weighted MRI images, ganglioneuromas demonstrate hypointensity. On T2-weighted images, they show heterogeneous but marked hyperintensity.

Adrenal Angiosarcomas

Angiosarcomas are malignant mesenchymal tumors that originate from the smooth muscle of the walls of adrenal veins. These tumors generally appear vascular on imaging studies.

Primary Malignant Melanoma

Primarily malignant melanoma of the adrenal glands is extremely rare. This tumor can occur within the adrenal gland because of the neuroectodermal origin of the adrenal medulla. Chromaffin cells and melanocytes have a common embryogenesis and similar histologic appearance. For a diagnosis of primary adrenal melanoma, the patient must have unilateral involvement of the adrenal, no previous history of melanoma, and an absence of extra-adrenal lesions.

Percutaneous Adrenal Biopsy

Percutaneous biopsy of an adrenal mass has become a standard diagnostic procedure for evaluating adrenal abnormalities. The most common indication for an adrenal biopsy is to exclude metastasis in patients with a known malignancy. Biopsy is also performed to identify primary adrenal tumors, infectious disease of the adrenal gland, and adrenal hemorrhage.⁷⁹

Adrenal biopsy is generally performed under CT guidance, which gives superior spatial resolution for visualizing the deep retroperitoneum. The *coaxial* technique, in which a guiding needle is placed next to the lesion, is performed (Fig. 40–29). Through the guiding needle, multiple passes can be made with a biopsy gun to obtain a significant amount of tissue for cytologic and histologic studies.

For the right adrenal gland, the approach to biopsy is generally transhepatic or posterior; for the left adrenal gland, the approach is generally posterior. For a posterior approach to either adrenal gland, the patient is placed in the decubitus position with the biopsy side down. This position helps to prevent the lung from intervening along the biopsy path. The anterior approach to the left adrenal gland is generally avoided because of the close proximity of the pancreas and vascular structures, which can increase the risk of complication.

The patient's breathing should be controlled during percutaneous adrenal biopsy because of the proximity of the pleura and the lung. The use of full expiration generally helps to obtain very reproducible results, acts as a breathing marker, and does not allow lung tissue to intervene through the chosen pathway. An 18-gauge biopsy gun can obtain cores of tissue for histologic study. When tracking deep into the retroperitoneum, these larger needles tend to be deflected less often compared with thinner needles. There is no difference in the complication rates for 18-gauge needles compared with needles used for smaller lesions.

The accuracy of image-guided biopsy of the adrenals generally approaches 95% in experienced hands.⁷⁹ The complication rate is 3%. The most common complication is adrenal hemorrhage because of the unique blood supply and the gland's vascular dam physiology. Most complica-

Figure 40–29. Possible adrenal metastases in a 66-year-old patient. *A*, Large infiltrating right adrenal mass. *B*, Transhepatic biopsy specimen of adrenal metastases in the right adrenal gland.

tions are benign and self-limiting and do not require surgery.

Pneumothorax and pancreatitis, two other potential major complications, can be minimized by:

1. Avoiding the pancreas by not using an anterior approach to the left adrenal gland.
2. Ensuring that no lung tissue intervenes along the path of the biopsy needle.

Percutaneous adrenal biopsy has become important for evaluating adrenal pathology and has reduced the use of more invasive procedures. A new trend in percutaneous intervention is the use of percutaneous ablation.^{40, 76} Generally applied to malignant tumors, percutaneous ablation is performed by injection of alcohol or by radiofrequency heating devices. Use of the technique has been limited in the adrenal gland, although adrenal cyst ablation and functioning adrenal tumor ablation using percutaneous injection of either absolute alcohol or acetic acid has been performed (Fig. 40–30).^{40, 76} The exact role of percutaneous ablation for other adrenal conditions continues to evolve and appears to have a promising future.

Multiple Endocrine Neoplasia

MEN comprises a group of disorders in which tumor or hyperplasia develops in two or more endocrine organs in a

single patient. It exists as three main types: MEN1, MEN2A, and MEN2B.⁵⁷ Autosomal dominant inheritance occurs in all three types.

MEN Type 1

MEN1 primarily affects the adrenal cortex by the formation of either nodules or functioning adenomas. Rarely do functional adrenal cortical adenomas occur; if they do, they present as either hyperaldosteronism or Cushing's syndrome. The other endocrine abnormalities involved with MEN1 include parathyroid hyperplasia or adenoma, gastrinoma, insulinoma, vipoma, and glucagonoma of the pancreatic islet cells. The anterior pituitary gland can be involved through adenomas that secrete prolactin, growth hormone, or ACTH. Carcinoid tumors can also occur, as can multiple lipomas and thyroid nodules.

MEN Types 2A and 2B

MEN2A is characterized by pheochromocytomas in the adrenal medulla. Associated medullary thyroid carcinoma and parathyroid hyperplasia or adenomas may occur. MEN2B is characterized by pheochromocytomas of the adrenal medulla and by medullary thyroid carcinoma, soft tissue neuromas, and ganglioneuromatosis of the intestine

Figure 40–30. Adrenal cyst. A, Contrast-enhanced CT scan of the abdomen reveals a 3-cm cyst in the left adrenal gland. B, Percutaneous sclerosis of the cyst was performed from a posterior approach. C, Follow-up CT scan demonstrates ablation of the left adrenal cyst.

with Marfan-like build. The pheochromocytomas that occur in MEN2A and MEN2B are often smaller than isolated intra-adrenal pheochromocytomas and more frequently bilateral. An increased incidence of extra-adrenal pheochromocytomas also occurs in patients with MEN2A or MEN2B.

Carney's Syndrome

Carney's syndrome is a related disorder characterized by the presence of gastric leiomyogenic neoplasms, extra-adrenal pheochromocytomas or paragangliomas, and pulmonary chondromas. Accurate imaging to define the extra-adrenal pheochromocytomas or paragangliomas, which are often functional, is important for preoperative localization. The combination of MIBG scanning with MRI or CT has been successful.

The Kidney

Vikram Dogra

Errol Levine

Computed tomography (CT) is a rapid, easily performed, and safe diagnostic imaging technique that provides valuable information about a wide spectrum of renal disorders. CT is highly accurate for determining the nature and extent of renal masses and plays a valuable role in assessing patients with renal cystic disease, renal trauma, renal infections, renal blood flow disturbances, and hydronephrosis of unknown cause. Multidetector CT (multislice CT) promises to provide even more rapid assessment of the kidneys and a higher accuracy in the evaluation of renal masses and of the renal blood vessels than is currently provided by single-detector helical CT.

The technology of magnetic resonance imaging (MRI) has advanced rapidly, and MRI is now almost equivalent to CT in detecting and characterizing renal masses. However, because CT is less expensive, quicker, and more generally available, renal MRI is mainly used for evaluating patients in whom CT findings are equivocal or contrast-enhanced CT is contraindicated because of (1) previous reactions to intravenous iodinated contrast medium or (2) the presence of renal failure.

This chapter has been fully revised with updated information and most current references; additional images have also been included. The introduction of new applications of CT, such as in the evaluation of renal stone study protocol, is also discussed, as are newly described entities, such as medullary carcinoma. This chapter addresses and analyzes the most updated roles of CT and MRI in urologic diagnosis.

Normal CT Anatomy

The kidneys are surrounded by perinephric fat, which in turn is enveloped by a dense connective tissue sheath called the renal fascia (Fig. 41-1). The anterior renal fascia (Gerota's fascia) covers the kidney anteriorly, while the posterior renal fascia (Zuckerkandl's fascia) covers the kidney posteriorly (Fig. 41-1). The renal fascial layers divide the general retroperitoneal space into three compartments extending from the diaphragm to the pelvic brim—the anterior pararenal space, the perinephric space, and the posterior pararenal space (see Fig. 41-1).¹⁸¹ Because it differentiates between fat and fascial tissue, CT usually shows the renal fascia and major extraperitoneal compartments (Fig. 41-2).

Perinephric Space

The perinephric space contains the kidney, adrenal gland, inferior vena cava, lower aorta, renal pelvis, proxi-

mal ureter, renal blood vessels, renal capsular vessels, and perinephric fat (see Fig. 41-1). It is bound by the anterior and posterior renal fascial layers and is demarcated by their sites of fusion. Above the adrenal glands, the two fascial layers fuse and adhere firmly to the diaphragmatic fascia; laterally the layers fuse behind the ascending or descending colon to form the lateroconal fascia (see Fig. 41-1). Medially, the anterior renal fascia blends into the connective tissue near the midline (see Fig. 41-1)^{74, 181}; the posterior

Figure 41-1. Transverse (A to C) and parasagittal (D) sections of the left flank. Sections A to C show the cross-sectional anatomy at the three levels indicated in D—the level of the renal hilus (A), the lower renal pole (B), and above the iliac crest (C). In D, the approximate positions of the psoas and quadratus lumborum muscles (stippled areas) are indicated by dashed lines. AO = aorta; PS = psoas muscle; QL = quadratus lumborum muscle; LK = left kidney; LRP = left renal pelvis; UR = ureter; PP = parietal peritoneum; ARF = anterior renal fascia; PRF = posterior renal fascia; LC = lateroconal fascia; DS = deeper stratum of renal fascia; DC = descending colon; 1 = anterior pararenal space; 2 = perinephric space; 3 = posterior pararenal space; D = diaphragm; LA = left adrenal; FC = fibrous capsule of kidney; TF = transversalis fascia; IL = iliopsoas muscle. (From Feldberg MA, Koehler PR, van Waes PF: Psoas compartment disease studied by computed tomography: Analysis of 50 cases and subject review. *Radiology* 148:505-512, 1983.)

Figure 41-2. Normal CT anatomy. The posterior renal fascia (open arrows) separates the perinephric and posterior paranephric spaces. The anterior renal fascia (straight white arrow) separates the perinephric and anterior paranephric spaces. The lateroconal fascia (black arrow) extends lateral to the descending colon (curved arrow).

renal fascia fuses with the psoas or quadratus lumborum fascia. The renal fascial cone extends inferior to the kidney, forming a caudal extension of the main perinephric space containing the proximal ureter and gonadal vessels (see Fig. 41-1).¹⁸¹ Right and left perirenal spaces communicate with each other anterior to the inferior vena cava and below the level of the renal hilum.^{11, 271}

The perinephric space is divided into multiple compartments by fibrous lamellae, the bridging septa (Fig. 41-3).^{2, 136} Some arise from the renal capsule and extend to the anterior or posterior renal fascia. Others are attached only to the renal capsule and are arranged nearly parallel to the renal surface (see Fig. 41-3). One of the more constant of

Figure 41-3. Bridging septa in perinephric space. Multiple delicate fibrous bridging septa traverse the upper part of the left perinephric space. K = kidney.

these is the posterior renorenal bridging septum. It arises from the renal capsule at its posteromedial aspect and runs nearly parallel to the posterior surface of the kidney, inserting into the posterolateral aspect of the renal capsule. Still other bridging septa directly connect the anterior and posterior leaves of the renal fascia.¹³⁶ The bridging septa determine the distribution of blood, pus, or urine collections in the perinephric space.^{2, 136}

Kidneys

On CT, the transverse contour of the kidney is smooth and oval, with an anteromedial break in the renal outline at the hilus where the vascular pedicle enters (Fig. 41-4). The renal sinus is a potential space contained by the renal parenchyma. The space is filled with fatty tissue and contains the renal arteries, veins, lymphatics, and pelvicalyces. The renal sinus fat is directly continuous with the perinephric fat through the renal hilus. On unenhanced CT scans, the normal renal parenchyma has an attenuation value of 30 to 50 Hounsfield Units (HU), depending on patient hydration, and the cortex and medulla show no visible density differences.

After a rapid, intravenous injection of contrast medium, helical CT scanning shows a cortical nephrogram in which there is clear demarcation of the renal cortex and columns of Bertin from the renal medulla (Fig. 41-5). However, the cortical nephrogram phase is transient and a homogeneous tubular nephrogram rapidly develops (see Fig. 41-5). The renal veins are usually densely opacified during dynamic CT scanning and are shown anterior to the renal pelvis as tubular structures joining the inferior vena cava. However, during dynamic scanning the inferior vena cava often shows significantly less contrast enhancement than the renal veins; this difference is due to mixing of opacified blood from the renal vein and unopacified blood from the lower extremities (Fig. 41-6). This appearance should not be mistaken for vena caval thrombosis or tumor extension.

Figure 41-4. Normal CT renal anatomy. The longer left renal vein (open arrow) passes between the aorta (a) posteriorly and the superior mesenteric artery (curved arrow) anteriorly. It joins the inferior vena cava (v) at the level of the uncinate process of the pancreas (p). The right renal vein (arrow) is shorter.

Figure 41-5. Normal CT. *A*, The corticomedullary phase demonstrates dense enhancing cortex with minimal enhancement of renal medulla. *B*, After a brief delay, the parenchymal enhancement becomes uniform, resulting in the nephrographic phase; in late nephrographic phase calyces may be opacified.

The longer left renal vein crosses the retroperitoneum between the aorta posteriorly and the superior mesenteric vessels anteriorly, and joins the inferior vena cava at the level of the uncinate process of the pancreas. The right renal vein usually has a shorter, more oblique course (see Figs. 41-4 and 41-6). The renal arteries are located posterior to the renal veins and are usually smaller. Normal renal arteries are seen by helical (spiral) CT, performed during breath-holding with the use of narrow scan collimation.²³⁰

Developmental renal anomalies and minor anatomic variants are commonly encountered and are usually evaluated by excretory urography. However, CT is sometimes necessary for further evaluation when urographic findings are confusing (Figs. 41-7 and 41-8). For example, on excretory urography, renal sinus lipomatosis may masquerade as a mass lesion in the renal sinus. CT reveals the benign nature of the process by showing that the renal sinus is occupied by tissue with a fat-attenuation value. Normal variants, such as a dromedary hump in the left

Figure 41-6. Normal renal vasculature. In the corticomedullary phase, the renal veins (*long arrow*) and arteries (*short arrow*) have maximal opacification. The inferior vena cava (*medium arrow*) appears less dense because of mixing of opacified blood from the renal vein and unopacified blood from the lower extremities. This appearance should not be confused with vena caval thrombus.

Figure 41-7. Horseshoe kidney. *A*, Unenhanced scan shows staghorn calculi involving both elements of a horseshoe kidney. *B*, Contrast-enhanced CT scan shows malrotation of both kidneys with the renal pelvises directed anteriorly. The kidneys are joined by an isthmus (*arrow*) of functioning renal parenchyma.

Figure 41-8. Agenesis of the right kidney and congenital left ureteropelvic junction obstruction in an infant. The left renal pelvis (P) is markedly dilated, and there is also calyceal dilatation (arrowheads).

kidney and prominent columns of Bertin, may simulate renal masses on excretory urography. CT easily recognizes these variants, which enhance to the same degree as normal renal parenchyma after intravenous administration of contrast medium.

CT Technique

Single-detector and multidetector spiral CT have dramatically refined the diagnostic evaluation of renal disorders by allowing rapid image acquisition through the entire kidney during various phases of contrast enhancement after the administration of a single bolus of intravenous contrast material.^{133, 265} The technique should be tailored according to the specific clinical problem involved. However, there are some aspects common to all dedicated renal CT studies. Since unopacified bowel loops may simulate perinephric masses and retroperitoneal adenopathy, patients undergoing renal CT should receive oral contrast medium.

CT protocol for evaluation of the kidneys consists of both nonenhanced and contrast-material enhanced CT scans obtained in suspended respiration, to overcome the motion artifact. To avoid artifactual differences in attenuation values, the same peak kilovoltage, milliamperere-second setting, section thickness, and field of view should be used for both precontrast and postcontrast scans when small renal masses are being evaluated. The accuracy of attenuation values should also be tested by measuring the attenuation value of the gallbladder contents before and after intravenous administration of contrast medium. Apparent enhancement of the gallbladder contents suggests that mild enhancement of a renal mass may be spurious.²⁶

Images should be acquired with 1- to 3-mm collimation, subsecond scan time, and a pitch of up to 2:1 to allow coverage of the area of interest in single breath-hold. Multislice scanners allow 1- to 2.5-mm slices through the region of interest in single breath-hold. Unenhanced scans permit contrast enhancement of a renal lesion to be measured and also ensure that renal parenchymal calcifications, renal calculi, renal and perinephric hemorrhage and fat, and calcification in a renal mass will not be obscured by

contrast medium. Unenhanced scans also help differentiate hyperdense cyst from renal solid tumor.²⁴⁴

Corticomedullary Phase. Administration of intravenous contrast medium is a fundamental requirement for CT evaluation of most renal lesions. Enhancement of a mass indicates that the lesion is vascular and is therefore possibly a neoplasm. Contrast medium should be administered rapidly with a mechanical injector via an antecubital vein as a 150-mL bolus containing 40 to 45 g of iodine at a rate of 2 to 4 mL per second. The corticomedullary phase occurs between 25 and 70 seconds after the start of contrast administration. The corticomedullary phase begins as contrast material enters the cortical capillaries and peritubular spaces and filters into the proximal cortical tubules.²³⁴ Renal cortex can be differentiated from renal medulla at this stage because (1) the vascularity of the cortex is greater than that of the medulla and (2) contrast material has not yet reached the distal aspect of the renal tubules (Fig. 41-9).^{68, 234} The resultant CT nephrogram has been termed a *cortical nephrogram*. Corticomedullary phase images should always be obtained when information about the renal vasculature is desired or when there is a possibility that a detected renal mass may represent an aneurysm or an arteriovenous malformation or fistula.²⁹⁶ Maximal opacification of the renal vein and arteries occurs during this phase, allowing confident diagnosis of tumor extension to the vein.

Nephrographic Phase. This begins as contrast material proceeds from the cortical vessels and extracellular-interstitial space and enters the loops of Henle and collecting tubules. A homogeneous or tubular nephrogram results in which corticomedullary differentiation is lost (Fig. 41-10).¹⁸ The nephrographic phase starts about 80 seconds and lasts up to 180 seconds after the start of injection, and offers the best opportunity for discrimination between the normal renal medulla and a renal mass.^{265, 296} The nephrographic phase is the most valuable for detecting renal masses and characterizing indeterminate lesions.^{17, 41, 265}

Excretory Phase. Approximately 180 seconds after the start of contrast injection, the excretory phase begins. The

Figure 41-9. Corticomedullary phase. The corticomedullary phase demonstrates dense enhancing cortex with minimal enhancement of renal medulla.

Figure 41-10. Nephrographic phase. The renal parenchyma enhances uniformly, and corticomedullary differentiation is lost.

contrast material is excreted into the collecting system, so the attenuation of the nephrogram progressively decreases (Fig. 41-11). This phase is occasionally helpful to better delineate the relationship of a centrally located mass with the collecting system.²⁴⁴ This phase is also useful for evaluating urothelial masses.

MRI Techniques and Anatomy

Gadolinium-enhanced renal MRI is attractive as an alternative to other techniques for evaluation of native and transplanted kidneys, because it can be used in patients with renal failure or iodine allergies.²²⁴

Dynamic gadolinium-enhanced gradient-echo imaging achieves coverage of the entire kidney during breath-hold-

Figure 41-11. Excretory phase. The attenuation of the nephrogram progressively decreases, and calyces demonstrate contrast. Left kidney shows renal carcinoma.

ing, thereby reducing respiration-induced phase artifacts.²⁴⁰ Gadolinium-enhanced fat-suppressed T1-weighted spin-echo technique images the kidneys with significantly fewer artifacts than does conventional spin-echo imaging.²⁴¹ The ability of dedicated renal CT scanning and gadolinium-enhanced MRI to detect and characterize renal lesions greater than 1 cm is similar, although MRI is superior in detecting polar lesions because of its ability to image directly in nonaxial planes.²²³ Since CT is generally available, quicker, and less expensive than MRI, it is usually preferred to MRI for evaluating patients with suspected renal masses.

MRI is the preferred modality, however, for determining the cephalic extent of an intracaval tumor in a patient with renal cell carcinoma when this finding is not adequately documented by CT.²⁰⁹ Other indications for renal MRI are differentiation between hemorrhagic renal cysts and renal neoplasms, characterization of small renal masses that are indeterminate on CT or ultrasonography,²⁶ evaluation of renal donors,³⁰¹ visualization of renal blood vessels (MR angiography [MRA]),²³⁵ and evaluation of transplanted kidneys.¹⁰⁸

The MRI pulse sequences and the precise imaging parameters used depend on the nature of the available MRI equipment and on the clinical problem. Conventional spin-echo sequences may be used for evaluating the kidneys; the development of newer and faster imaging techniques, such as fast spin-echo and gradient-echo imaging, are preferred. T1-weighted, gradient-echo, in- and out-of-phase images from the top of the liver to the inferior pole of the kidney are obtained to study the anatomy and also evaluate the liver for any metastatic disease from renal tumor. This technique also allows assessment of the presence of fat within the renal lesion.

A T2-weighted fast spin-echo sequence with fat saturation is obtained in axial plane corresponding to the T1-weighted gradient sequence. Coronal T2-weighted (very long echo time [TE], such as half-Fourier acquisition single-shot turbo spin-echo [HASTE] and single-shot fast spin-echo [SSFSE]) images are also acquired to identify renal cysts. T1- and T2-weighted sequences help identify hemorrhagic cysts (Fig. 41-12). Gradient-echo images are helpful for evaluating renal masses.

Precontrast images of the kidneys are first obtained (Fig. 41-13). A 2D or 3D gradient-echo breath-hold sequence with and without gadolinium enhancement is obtained in the arterial phase (corticomedullary phase; 20 seconds), venous phase (nephrographic phase; 70 seconds), and delayed phase (excretory phase; 180 seconds). Gadopentetate dimeglumine (Gd) is injected intravenously by power injector in a dose of 0.1 to 0.2 mmol/kg over 5 seconds with the patient positioned in the bore of the magnet. The coronal plane is often advantageous because it allows evaluation of both kidneys, renal vessels, and the inferior vena cava.²⁰⁹ Imaging is started during breath-holding at 20 seconds after a rapid saline flush of the intravenous catheter has been performed. Images are also obtained at 70 seconds and 3 minutes after the start of injection.

Corticomedullary phase imaging demonstrates corticomedullary differentiation and also significant enhancement of the renal vein blood (see Fig. 41-13). This phase is optimal for assessing tumor extension to the veins. The

Figure 41-12. Hemorrhagic cyst. A, Axial T1-weighted gradient images demonstrate a small right renal upper pole cyst with increased signal (arrow). B, Corresponding T2-weighted image demonstrates increased signal (arrow) compared with the renal cortex. Previously diagnosed fibrous dysplasia of left ninth rib is incidental finding.

nephrographic phase is the best sequence to detect a renal mass.

Renal Cysts

Renal cysts usually represent notably dilated nephrons or collecting ducts.⁸³ A cystic kidney is a kidney with three to five or more cysts. The term *renal cystic disease* refers to any disorder that results from the presence of multiple renal cysts.

Simple Cysts

Simple cysts are the most common renal masses. Most are clinically insignificant, being discovered incidentally at autopsy or on imaging studies. Their frequency increases with age, with only rare examples reported in children. Although the cause of renal cysts is unknown, their frequent occurrence in older patients suggests that they are acquired lesions.¹⁹⁸ Although most simple cysts are asymptomatic, they occasionally cause pressure symptoms because of their large size, and cyst hemorrhage or infection

Figure 41-13. Normal renal MRI. A T1-weighted (gradient, out-of-phase) image (A) and a T2-weighted axial image (B) demonstrate the normal appearance of the kidneys. C, T1-weighted axial gadolinium-enhanced images reveal normal enhancing renal parenchyma. Renal vein (arrow) and renal artery (arrowhead) are also seen.

Figure 41-14. Simple renal cyst. Unenhanced (A) and contrast-enhanced (B) CT scans show that the mass is round, with a smooth margin and distinct margination from adjoining renal parenchyma. It has a homogeneous water density and does not enhance (precontrast and postcontrast attenuation value = 7 HU) and has no discernible wall thickness.

may cause pain and hematuria. Simple renal cysts may be solitary or multiple and are commonly bilateral. Ultrasonography is usually considered the most appropriate next investigation for further evaluation of a presumed renal cyst discovered on excretory urography. However, renal cysts are currently often found on abdominal CT scanning performed for nonrenal complaints. Such cysts may vary in size from less than 1 cm to 10 to 15 cm (Figs. 41-14 and 41-15).

CT Features

The accuracy of CT diagnosis of a simple renal cyst approaches 100% if a renal mass strictly fulfills the following well-established criteria: (1) sharp margination and

demarcation from surrounding renal parenchyma, (2) a smooth, thin wall, (3) a homogeneous, water-density content with an attenuation value of 0 to 20 HU, and (4) no enhancement after intravenous administration of contrast medium (see Fig. 41-14).^{24, 170} If a renal mass fulfills these CT criteria, no further evaluation is necessary.

In routine CT, performed for nonrenal complaints, usually only intravenous contrast-enhanced scanning is performed; therefore, the presence or absence of contrast enhancement in renal masses often cannot be determined.²⁴ A simple cyst can usually be diagnosed even without this information, however, if the other CT criteria listed previously are fulfilled (see Fig. 41-15).²⁴ If CT findings are atypical or if the patient is referred because of symptoms such as hematuria, nonenhanced scans should also be obtained. Obtaining both sets of scans permits contrast enhancement to be measured and also precludes misinterpretation of nonenhancing high-density renal cysts as solid renal masses.²⁴

Although CT is accurate in diagnosing simple renal cysts, interpretation of CT findings has some potential pitfalls. Small renal cysts may be volume-averaged with normal renal tissue, causing spuriously high attenuation values,¹⁷⁰ or falsely high attenuation values may be caused by streak artifacts.²⁶ In these circumstances, ultrasonography should be performed to determine whether the lesion is a cyst or a neoplasm. If ultrasonographic findings are indeterminate, dedicated renal CT with special attention to the lesion should be performed.²⁴

MRI Features

The use of gadolinium-enhanced MRI, particularly with gradient-echo imaging techniques applied during breath-hold is helpful in the evaluation of renal cystic lesions in patients with contraindications to iodinated intravenous contrast medium, such as chronic renal failure or previous reactions to contrast media.^{224, 241} Even a small, simple renal cyst can be diagnosed on contrast-enhanced MRI if it fulfills the following criteria: (1) sharp margination and demarcation from surrounding renal parenchyma, (2) a

Figure 41-15. Simple renal cyst. Lesion (arrow) has attenuation value of 9 HU and was detected during survey CT scan performed only with intravenous contrast enhancement. Even though an unenhanced scan is unavailable, the diagnosis of a cyst can be made with confidence because of the low-attenuation value, smooth rounded shape, sharp margination, and demarcation from surrounding renal parenchyma and thin wall where the lesion projects beyond the renal outline.

Figure 41-16. Simple renal cyst in renal transplant shown by MRI. *A*, T1-weighted (TR = 500 msec, TE = 15 msec) spin-echo image shows lesion (arrow) with lower signal intensity than renal parenchyma. *B*, On T2-weighted (TR = 2200 msec, TE = 90 msec) spin-echo image, the cyst is hyperintense, indicating its fluid content. The cyst is well-defined and has a smooth wall (arrow). *C*, Postcontrast gradient-echo (TR = 168 msec, TE = 90 msec, flip angle = 75°) image obtained after intravenous injection of gadolinium-DTPA shows that the lesion (arrow) does not enhance.

smooth, thin wall, (3) homogeneous contents with signal characteristics of water (such lesions have a low signal intensity on T1-weighted spin-echo images and a high signal intensity on T2-weighted spin-echo images), and (4) no enhancement after intravenous injection of gadolinium-DTPA (diethylene triaminepenta-acetic acid) (Fig. 41-16).²⁴¹ Subsecond T2-weighted pulse sequence (SSFSE on GE machines and their equivalent on other machines) is better suited for detection of simple renal cysts, especially those smaller than 1 cm.¹⁸²

Atypical Cysts and Cystic Neoplasms

Many renal cystic lesions do not fulfill the criteria for simple cysts listed previously. Such lesions vary from minimally complicated simple cysts that usually do not require surgery to cystic renal neoplasms that generally need resection. Complicated cysts often result from bleeding in a simple cyst. Bosniak has suggested the categorization of cystic renal masses according to CT criteria in an attempt to separate lesions that require surgery from those that do not.²⁴ The application of Bosniak's classification is most useful in evaluating and managing cystic renal lesions.⁶

Category I Lesions. In Bosniak's classification, category I lesions are classic simple cysts as described pre-

viously (see Figs. 41-14 to 41-16). They require no further evaluation or management.

Category II Lesions. Category II lesions are minimally complicated cysts that also usually do not require surgery.

Figure 41-17. Minimally calcified benign cyst (arrow); category II lesion. A contrast-enhanced CT scan reveals fine linear calcification in the cyst wall and septa. The lesion shows a thin wall, and no focal nodules or areas of enhancement. The fluid in the cyst measured 12 HU.

Figure 41-18. Hyperdense benign renal cyst; category II lesion. Unenhanced CT scan (A) shows a high-density mass (92 HU) (*arrow*) located anteriorly in the kidney. On contrast-enhanced CT scan (B), the lesion (*arrow*) did not enhance; it is homogeneous and reveals a smooth margin where it projects beyond the renal outline.

Occasional thin (less than 1 mm), smooth septa, or small, smooth plaques of fine linear calcification in the cyst wall or septa occur in these lesions (Fig. 41-17).

Also included in category II are high-density cysts (Fig.

41-18). These lesions have attenuation values ranging from 40 to 100 HU on unenhanced CT scans and are usually caused by a high protein content or previous hemorrhage.¹²⁰ Most high-density renal cysts are benign and can simply

Figure 41-19. Hemorrhagic cyst in upper pole of left kidney. A, A contrast-enhanced CT scan shows a well-defined mass (*arrow*) in the upper pole of the left kidney. The lesion had a precontrast and postcontrast attenuation value of 45 HU. B, Gradient-echo (TR = 168 msec, TE = 16 msec, flip angle = 75°) MR image shows fluid iron level in cyst with high-intensity methemoglobin sediment located posteriorly (*arrow*) and lower-intensity cyst fluid located anteriorly. C, T2-weighted (TR = 2200 msec, TE = 90 msec) spin-echo image reveals that anteriorly located cyst fluid is hyperintense, whereas dependent sediment (*arrow*) has a lower signal intensity.

Figure 41-20. Hemorrhagic benign renal cyst; category III lesion. The lesion (arrow) shows thick, irregular mural calcification. The lesion has an attenuation value of 12 HU on an unenhanced CT scan (A) and shows no enhancement after contrast administration (B). The kidney was explored, and a local resection of the lesion was performed.

be monitored with serial imaging, provided that the following CT criteria are fulfilled: (1) the lesion must be perfectly smooth, round, sharply margined, and homogeneous; (2) the lesion should not enhance with intravenous contrast medium; (3) at least one fourth of the lesion's circumference should extend outside the kidney so that the smoothness of some of the wall can be evaluated; and (4) the lesion should be less than 3 cm in diameter.²⁶ Although most lesions meeting these criteria are benign hemorrhagic cysts,²⁵ cystic renal cell carcinoma may rarely show similar characteristics on CT.¹⁰⁰

MRI may also help in characterizing high-density renal cysts that do not fulfill all the preceding CT criteria or that show internal echoes on ultrasonography. Hemorrhagic cysts appear on MRI as sharply margined, smooth, round, homogeneous lesions. They have high signal intensity on both T1- and T2-weighted sequences,¹⁴⁶ and they do not enhance after intravenous administration of gadolinium-DTPA (see Fig. 41-16). In addition, hemorrhagic cysts often show fluid-iron levels on MRI, probably because of

dependent settling of methemoglobin containing sediment (Fig. 41-19).¹⁴⁶

Category III Lesions. Lesions in category III are more complicated cystic lesions. They exhibit some findings seen in malignant lesions, including thick, irregular mural or septal calcification (Fig. 41-20), numerous or thick (>1 mm), irregular septa (Fig. 41-21), and uniform or slightly nodular wall thickening.²⁴ Some category III lesions are benign (e.g., multilocular cystic nephromas and hemorrhagic renal cysts); others are cystic renal cell carcinomas (see Fig. 41-21). All such lesions should undergo surgical exploration, unless the procedure is contraindicated because of the patient's advanced age or poor general medical condition.²⁴

Category IV Lesions. Category IV lesions are clearly malignant lesions with large cystic components; they should be resected.²⁴ They may show marginal irregularity or solid vascular elements (Fig. 41-22).

Figure 41-21. Multilocular cystic renal cell carcinoma; category III lesion. A contrast-enhanced CT scan reveals a well-defined, mainly fluid-containing mass in the right kidney. Enhancing septa are seen throughout the lesion. A right nephrectomy was performed.

Figure 41-22. Cystic renal cell carcinoma; category IV lesion. Contrast-enhanced CT scan shows a cystic mass (arrow) with irregular and enhancing solid elements located anteriorly.

Figure 41-23. Renal sinus (parapelvic) cyst. A contrast-enhanced CT scan reveals that the cyst (*white arrow*) is surrounded by a halo of renal sinus fat, indicating its extrarenal origin. The nondilated collecting system (*curved arrow*) and ureter (*long arrow*) are displaced by the cyst.

Renal Sinus Cysts

Renal sinus (parapelvic) cysts are benign extraparenchymal cysts located in the renal sinus.¹⁰⁷ They are not true renal cysts, but are probably lymphatic in origin.¹⁰⁷ They may be unilocular or multilocular and are often bilateral (Figs. 41-23 and 41-24).¹⁰⁷ They do not communicate with the renal collecting system. Most renal sinus cysts are asymptomatic and are discovered incidentally on imaging studies.¹⁰⁷ They may in rare cases cause hypertension, hematuria, or hydronephrosis, or may become secondarily infected.

Renal sinus cysts display the same CT features as simple renal parenchymal cysts.¹⁰⁷ They have attenuation values in the water range (0 to 20 HU) and are difficult to distinguish from dilated or extrarenal renal pelvis on unenhanced CT scans. After intravenous administration of contrast medium, the cysts remain of water density and cause displacement of the renal pelvis and calyces (see Fig. 41-24). Differentiation from hydronephrosis is thus readily made on contrast-enhanced CT.¹⁰⁷ On CT, the characteristic

Figure 41-24. Bilateral renal sinus cysts. The cysts cause displacement and attenuation of the opacified collecting systems. A simple renal cyst is also present anteriorly in the left kidney (*arrow*).

feature of a renal sinus cyst is a surrounding halo of renal sinus fat, indicating its extrarenal origin (see Fig. 41-23).⁴⁴

CT easily distinguishes between a renal sinus cyst and renal sinus lipomatosis, which causes a similar deformity of the collecting system on excretory urography.¹⁰⁷ In renal sinus lipomatosis, the attenuation value of the tissue is in the fat range. Solid masses in the renal sinus, such as lymphoma and invasive transitional cell carcinoma, are readily differentiated from renal sinus cysts because of their soft tissue attenuation values.

Renal Cystic Disease

Renal cystic disease includes a wide variety of disorders. Although imaging studies help greatly in the evaluation of renal cystic disease, they are seldom diagnostic per se because many types of cystic kidneys show similar imaging findings. Therefore, interpretation of imaging findings should always include knowledge of the patient's age, family history, symptoms, clinical findings, and renal functional status.

Multicystic Dysplastic Kidney

Multicystic dysplastic kidney (MDK) is the most common form of cystic disease in infants, usually presenting as an asymptomatic flank mass. The disorder is associated with intrauterine ureteral obstruction or atresia.²³³ The renal artery may also be hypoplastic or atretic.¹⁹⁷ Contralateral renal anomalies are detected in 41% of patients with MDK and include obstruction of the ureteropelvic junction, renal agenesis, renal hypoplasia, vesicoureteral reflux, and bilateral MDK. Bilateral MDK is seen in 19% and contralateral agenesis is seen in 11% of patients with MDK.¹³⁰ Two types of MDK may be shown by imaging, pelvo-infundibular atresia and the hydronephrotic type.²⁶¹ In the classic type, pelvo-infundibular atresia, no discernible renal pelvis is demonstrated on imaging.²³² The kidney may be small, normal in size, or enlarged and contains multiple variably-sized noncommunicating renal cysts (Fig. 41-25).^{197, 232} No perfusion of the affected kidney occurs on renal scintigraphy, and contrast-enhanced CT shows no evidence of contrast excretion by the affected kidney.²⁶¹

Figure 41-25. Multicystic dysplastic kidney in a neonate. The right kidney was replaced by cysts (*c*), one of which is larger than the other. The right kidney did not excrete contrast medium. The left kidney is normal.

Figure 41-26. Multicystic dysplasia of left kidney in a 27-year-old man with microscopic hematuria. The left kidney is small and is composed of cysts with mural calcification (arrow). There is compensatory hypertrophy of the right kidney.

The hydronephrotic form of MDK is characterized by dilatation of the renal pelvis and calyces. Differentiation of this type of MDK from simple hydronephrosis is based on the imaging demonstration of parenchymal cysts that do not communicate with the collecting system.^{197, 232} Currently, most cases of unilateral MDK are managed nonsurgically and are followed with serial ultrasonography.^{188, 197} The affected kidney may remain unchanged, but it frequently undergoes spontaneous regression.^{197, 281} MDK may occasionally be detected first in adults in whom imaging studies show a small kidney with calcified cysts (Fig. 41-26) or an enlarged dysfunctional kidney.²⁶⁴ T2-weighted pulse sequence can be used to diagnose MDK, especially in utero.¹¹⁰

Polycystic Kidney Disease

Hereditary polycystic kidney disease may be transmitted as an autosomal recessive or autosomal dominant trait.

Autosomal Recessive Polycystic Disease

Autosomal recessive polycystic kidney disease (ARPKD) is characterized by ectasia of the renal collecting ducts, interstitial fibrosis, and variable degrees of portal hepatic fibrosis (congenital hepatic fibrosis), which often causes portal hypertension.¹⁵⁸ Ten percent to 90% of the collecting ducts are involved. Severity of the disease depends on, and is inversely related to, the age at presentation. Patients with milder renal involvement may present at any age from infancy to early adulthood. The severity of renal involvement and extent of liver involvement in these patients are inversely related. On noncontrast CT examination, the kidneys are smooth, enlarged, and low in attenuation, likely a reflection of the large fluid volume in the dilated ducts. Upon administration of contrast medium, a *striated nephrogram* is seen, representing accumulation of contrast in the dilated tubules. Tubular ectasia is confined mainly to the renal medulla with only occasional macrocysts. The renal cortex is less severely affected (Fig. 41-27).¹⁵⁸ CT may also show evidence of congenital hepatic fibrosis and portal hypertension.⁴⁸ The liver contour is often irregular, and dilated intrahepatic bile ducts, ascites, splenomegaly, and enlarged portal-systemic collateral veins may be seen (Fig. 41-28). Liver cysts are not usually

Figure 41-27. Autosomal recessive polycystic kidney disease in a 30-month-old infant with normal renal function. A contrast-enhanced CT scan shows dilated collecting ducts in the renal medulla (striated nephrogram) bilaterally and relative preservation of the renal cortex. Occasional macroscopic cysts (arrowheads) are present in the left kidney.

Figure 41-28. Autosomal recessive polycystic kidney disease in a 14-year-old girl with normal renal function. *A*, The liver contour is irregular as a result of congenital hepatic fibrosis. The spleen (S) is enlarged because of portal hypertension. Ascites (a) is present, and there is an enlarged left gastric vein (arrow) in the hepatogastric ligament. *B*, A more caudal scan shows mild nephromegaly and multiple medullary cysts with relative preservation of the renal cortex. (From Levine E: Computed tomography of renal masses. Crit Rev Diagn Imaging 24:91-200, 1985.)

evident. However, some patients have large liver cysts of biliary origin because of the presence of Caroli's disease.⁵⁴ Increased signal intensity of renal parenchyma is seen on T2-weighted MRI in ARPKD.^{127, 128, 183}

Autosomal Dominant Polycystic Kidney Disease.

ADPKD is one of the most commonly inherited diseases in the United States. It affects nearly 500,000 Americans and accounts for 5% to 10% of patients with end-stage renal disease (ESRD).¹² ADPKD comprises at least three phenotypically indistinguishable but genetically distinct entities, caused by mutations in three autosomal genes: PKD1 (chromosome 16p13.3) is present in about 85% of patients; PKD2 (chromosome 4q21-23) in 10%; PKD3 (unknown chromosome) in a few families.²⁴² The mean patient age at presentation with symptoms in ADPKD-1 is 44.8 years, versus 69.1 years for ADPKD-2.¹⁹³ New mutations or non-familial development of ADPKD occurs in 1% to 2% of ADPKD. Whites of European descent have the highest disease rates.³³ ADPKD is associated with severely impaired renal function, but only 2% to 5% of the nephrons are directly affected by the cystic changes.³⁵ Only 35% to 45% of patients with ADPKD experience ESRD.³⁹

Cysts originate from renal tubules and collecting ducts. The ADPKD genotypes are characterized by bilateral kidney cysts, hypertension, hematuria, renal infection, stones, and renal insufficiency. ADPKD is a systemic disorder; cysts appear with decreasing order of frequency in the kidneys, liver, pancreas, brain, spleen, ovaries, and testis. Cardiac valvular disorders, abdominal and inguinal hernias, and aneurysms of cerebral and coronary arteries and the aorta are also associated with ADPKD. Colonic diverticula occur in about 80% of patients with the disease.⁷⁶

Although the disorder usually manifests in adults (Fig. 41-29), it may be diagnosed during infancy and childhood. Patients with fully developed ADPKD often show dramatic CT findings (see Fig. 41-29). CT is slightly more sensitive than ultrasonography for detecting small renal cysts in the asymptomatic progeny of patients with ADPKD (Fig. 41-30).⁸²

Figure 41-30. Autosomal dominant polycystic kidney disease in an asymptomatic 14-year-old boy whose father has the disease. A contrast-enhanced CT scan shows multiple, tiny bilateral renal cysts.

Flank pain and hematuria, the most common symptoms of ADPKD, may be due to cyst hemorrhage, calculi, or renal infection. Cyst hemorrhage is a common cause of pain in ADPKD and can be detected by CT in about 69% of patients.¹⁴⁵ Hemorrhagic cysts have attenuation values of 40 to 100 HU on unenhanced scans, do not enhance after intravenous administration of contrast medium, and are homogeneously hyperdense and well defined (Fig. 41-31). Pseudoenhancement of 10 Hu can be seen in cysts smaller than 2 cm.⁴² They may rupture into the perinephric space, causing large hematomas (Fig. 41-32).¹⁴⁶ Hemorrhagic cysts often develop mural calcification (Fig. 41-33).

Renal calculi occur in 20% to 36% of patients with ADPKD, and they commonly cause flank pain.¹⁴⁴ About 57% of calculi in ADPKD are composed predominantly of uric acid and are therefore radiolucent on conventional tomography.²⁷³ Such calculi are best evaluated by CT (Fig. 41-34).¹⁴⁴ Urinary tract infections are more common in women with ADPKD and may cause cyst infection. Cyst infection is difficult to diagnose on CT; it is suggested by the finding of a cyst larger than surrounding cysts with

Figure 41-29. Autosomal dominant polycystic kidney disease in a 39-year-old man with hypertension and mildly impaired renal function. Unenhanced CT scan (A) shows bilateral nephromegaly. Contrast-enhanced CT scan (B) reveals large renal cysts with enhancing residual parenchyma between the cysts.

Figure 41-31. Hemorrhagic renal cysts in autosomal dominant polycystic kidney disease. *A*, Unenhanced CT scan shows bilateral subcapsular high-density cysts (arrows). *B*, After IV contrast enhancement, the high-density cysts (arrows) are hypodense relative to enhanced residual renal parenchyma. Many fluid-density cysts are present. The high-density cysts had an average attenuation value of 70 HU on both precontrast and postcontrast scans.

Figure 41-32. Autosomal dominant polycystic kidney disease with perinephric hemorrhage. Unenhanced CT scan reveals bilateral nephromegaly and multiple cysts. A posterior perinephric hematoma (short arrows) causes anterior displacement of the left kidney. A ruptured hemorrhagic cyst (open arrow) communicates (long arrow) with the hematoma. (From Levine E, Grantham JJ: Perinephric hemorrhage in autosomal dominant polycystic kidney disease: CT and MR findings. *J Comput Assist Tomogr* 11: 108-111, 1987.)

Figure 41-33. Autosomal dominant polycystic kidney disease with multiple curvilinear calcifications in cyst walls.

Figure 41-34. Autosomal dominant polycystic kidney disease with a calculus in the lower pole of the left kidney. *A*, An unenhanced CT scan shows a small, rounded calcification (arrowhead). *B*, A contrast-enhanced CT scan reveals that the calcification is located in an opacified calyx (arrowhead). (From Levine E, Grantham JJ: Calcified renal stones and cyst calcifications in autosomal dominant polycystic kidney disease: Clinical and CT study in 85 patients. *AJR Am J Roentgenol* 159:77-81, 1992.)

Figure 41-35. Acute pyelonephritis complicated by cyst infection in autosomal dominant polycystic kidney disease. A lower pole cyst (solid arrow) is larger than adjacent cysts and shows an irregular, thickened wall and adjacent renal fascial thickening (open arrow). The patient demonstrated a response to antibiotic therapy, and a follow-up sonogram showed absence of the large cyst, suggesting rupture into the collecting system. (From Levine E, Grantham JJ: Calcified renal stones and cyst calcifications in autosomal dominant polycystic kidney disease: Clinical and CT study in 85 patients. *AJR Am J Roentgenol* 159:77-81, 1992.)

thickening and irregularity of its wall, an increase in the attenuation value of its contents, and localized thickening of the adjacent renal fascia (Fig. 41-35). Radionuclide scanning using gallium citrate 32 - or indium 111 -labeled white blood cells may help confirm the diagnosis of cyst infection by showing increased tracer activity at the cyst periphery.²³⁶

Cysts of the liver are present in 70% to 75% of cases of ADPKD. The cysts are thought to arise from Meyenburg's complexes. Hepatic cysts develop later than renal cysts and women are more commonly affected.³⁵ The CT appearance can vary from occasional small cysts (Fig. 41-36) to multi-

Figure 41-36. Multiple small liver cysts in autosomal dominant polycystic kidney disease.

Figure 41-37. Significant hepatomegaly caused by liver cysts in a 45-year-old woman with autosomal dominant polycystic kidney disease. (From Levine E, Cook LT, Grantham JJ: Liver cysts in autosomal-dominant polycystic kidney disease: Clinical and computed tomographic study. *AJR Am J Roentgenol* 145:229-233, 1985.)

ple, large cysts that cause hepatomegaly (Fig. 41-37). Abnormal liver function values suggest the development of such complications as common hepatic duct compression by cysts, cyst infection, and cholangiocarcinoma arising from the cyst lining (Fig. 41-38).^{149, 268} The risk of renal cancer in patients with ADPKD who are not undergoing dialysis is probably not increased; however, patients under-

Figure 41-38. Autosomal dominant polycystic kidney disease complicated by cholangiocarcinoma in a 69-year-old man complaining of abdominal pain and weight loss. Liver function values were notably abnormal. CT scan shows several cysts in the right lobe of the liver. A poorly defined, low-density mass (arrowheads) involves the left lobe and part of the anterior segment of the right lobe. Ascites (a) is present. The neoplasm was not resectable, and the patient died from metastatic disease. (From Levine E, Cook LT, Grantham JJ: Liver cysts in autosomal-dominant polycystic kidney disease: Clinical and computed tomographic study. *AJR Am J Roentgenol* 145:229-233, 1985.)

Figure 41-39. MRI of polycystic kidney. Coronal single-shot fast spin-echo images (TR = 67,500 msec, and effective TE = 637 msec) demonstrate nephromegaly with multiple cysts that have variable signal intensities secondary to hemorrhage or high protein content.

going dialysis are at greater risk for development of renal malignancy relative to the general population.³⁵

Living related kidney donors (with a family history of ADPKD) require screening for ADPKD, most commonly by ultrasonography. Ultrasound examination has a negative predictive value (NPV) of 100% for donors older than 30 years, but of only 96% for donors 20 to 30 years old. Heavily T2-weighted MRI in coronal and axial planes may be a more sensitive screening method for ADPKD in younger kidney donors (Fig. 41-39).³⁰¹

Unilateral (Localized) Renal Cystic Disease

In unilateral renal cystic disease (URCD), also known as localized renal cystic disease, most of one kidney is replaced by multiple cysts and the other kidney is normal. The affected patient usually has no family history of renal cysts, and the condition is not related to ADPKD.^{45, 132, 147, 250} Liver cysts and renal failure do not occur in this condition. Affected patients range in age from

childhood to the sixth decade and may have hypertension, flank pain, or hematuria.¹⁴⁷ On CT, the cysts are seen to be separated by enhancing bands of normal renal parenchyma so that no distinct encapsulated renal mass is found (Fig. 41-40). The affected kidney may be enlarged and shows normal excretion of contrast medium. Although the cysts may predominate in one part of the affected kidney, careful assessment of the CT scan usually shows multiple smaller cysts elsewhere in the renal parenchyma.¹⁴⁷

The absence of cysts in the other kidney on CT in adults usually excludes the diagnosis of ADPKD, but one must use caution in making a definitive diagnosis of URCD in children. In ADPKD, renal cysts develop slowly during childhood and may become apparent earlier in one kidney.²⁰⁵ Accordingly, in children, follow-up CT should be performed after an appropriate interval before a final diagnosis of URCD is made.

Acquired Cystic Kidney Disease

Acquired cystic kidney disease (ACKD) is characterized by the development of multiple renal cysts in patients with chronic renal failure but without a history of hereditary renal cystic disease.¹⁴⁰ ACKD is seen in 90% of patients after 5 to 10 years of renal dialysis (hemodialysis or peritoneal dialysis); however, ACKD may be encountered in as many as 8% to 13% of patients with ESRD who are not undergoing dialysis.^{119, 167} Nephrosclerosis, diabetic nephropathy, and chronic glomerulonephritis account for a large percentage of ACKD patients undergoing dialysis.¹⁶⁷ The condition is usually asymptomatic but may become symptomatic when associated with a complication such as cyst or retroperitoneal hemorrhage, cyst infection, renal calculi, erythrocytosis, or renal neoplasm.^{34, 140}

The radiologic diagnosis of ACKD is best established with contrast-enhanced CT, although ultrasonography and MRI are useful for evaluating patients with ESRD who are not being treated with dialysis. The diagnosis is based on detection of at least three to five cysts in each kidney in a patient who has chronic renal failure not due to hereditary renal cystic disease.¹⁵⁴ The affected kidneys are usually small (Fig. 41-41). However, ACKD is a progressive disorder, and nephromegaly may eventually develop (see Fig. 41-41).¹¹⁹ On MRI, renal cysts in ACKD are best shown on gadolinium-enhanced images (Fig. 41-42).

Hemorrhagic cysts occur in about 50% of patients with

Figure 41-40. Unilateral renal cystic disease in a 15-year-old male with intermittent gross hematuria starting at 5 years of age. Contrast-enhanced CT scans (A and B) show partial replacement of the left kidney by many cysts that are separated by enhancing bands of normal parenchyma. The right kidney is free of cysts, and a follow-up CT scan 7 years later showed no change.

Figure 41-41. Acquired renal cystic disease in a 45-year-old man undergoing long-term hemodialysis. *A*, CT scan after 4 years of dialysis shows bilateral small cysts in shrunken kidneys. *B*, A follow-up CT scan obtained 4 years later shows enlargement of cysts and kidneys.

ACKD and sometimes attain a large size.¹⁵³ On CT, hemorrhagic cysts manifest as well-defined masses with attenuation values ranging from 40 to 100 HU on unenhanced CT scans (Fig. 41-43). Differentiation of these lesions from renal neoplasms on CT is suggested by lack of contrast enhancement and a homogeneous appearance on contrast-enhanced CT scans (see Fig. 41-43).¹⁵³ A nonhemorrhagic cyst that is more than 1 cm in diameter may show pseudo-enhancement of less than 10 HU.⁷ Sonography may help in establishing the cystic nature of such a lesion by showing anechoic center, posterior acoustic enhancement, and a smooth wall. On MRI, hemorrhagic cysts often have high signal intensity on both T1- and T2-weighted images and do not enhance after gadolinium administration (Fig. 41-44). Subcapsular and perinephric hematomas, which occur in as many as 13% of patients with ACKD, are usually due to rupture of hemorrhagic cysts (Fig. 41-45).¹⁵³

The primary concern in patients with ACKD is the increased incidence (5% to 19%) of renal cell carcinoma (RCC). The incidence is about 12 to 18 times higher than

that in the general population, and the cancers may be asymptomatic (Fig. 41-46).¹¹⁹ RCC in patients undergoing dialysis occurs at an average age of 49 years, compared with 62 years in nonazotemic patients.²⁰⁶ The development of RCC in patients undergoing dialysis depends on the duration of dialysis (incidence rises after 3 years of dialysis), the size of the kidneys, and male gender (seven times higher).^{34, 140} Small renal neoplasms (<3 cm in diameter) are significantly more common than large carcinomas and occur in about 7% of patients undergoing dialysis (Fig. 41-47).¹⁴⁰ Most such lesions remain unchanged with prolonged follow-up. However, some gradually enlarge and may become locally invasive or even metastasize (see Fig. 41-47).¹⁵⁰ Because of their propensity to develop malignant renal neoplasms, the native kidneys of patients undergoing dialysis should be evaluated with CT if the patients experience flank pain or hematuria. Annual imaging of the native kidneys in asymptomatic patients undergoing dialysis should be restricted to those with a good general medical condition and a good life expectancy.¹⁵³

Figure 41-42. Acquired renal cystic disease and left renal cell carcinoma in a 59-year-old man with azotemia not treated with dialysis. *A*, T1-weighted (TR = 440 msec, TE = 17 msec) spin-echo MR image after gadolinium DTPA administration shows several well-defined cysts (arrowheads) of low signal intensity in the left kidney. *B*, T2-weighted (TR = 2100 msec, TE = 90 msec) image without gadolinium administration reveals a heterogeneous, 3.5-cm lower-pole carcinoma (arrowheads).

Figure 41-43. Acquired renal cystic disease with cyst hemorrhage in a 41-year-old man with gross hematuria. *A*, An unenhanced CT scan shows a 3.8-cm high-density (44 HU) mass (arrow) in the upper pole of the left kidney. *B*, After contrast enhancement, the attenuation value of the mass (arrow) was 43 HU. Multiple bilateral fluid-density cysts are also present. The mass resolved completely on a follow-up CT scan obtained 3 months later, suggesting a hemorrhagic cyst that had ruptured into the collecting system. (From Levine E, Slusher SL, Grantham JJ, Wetzel LH: Natural history of acquired renal cystic disease in dialysis patients: A prospective longitudinal CT study. *AJR Am J Roentgenol* 156:501-506, 1991.)

Figure 41-44. Hemorrhagic cysts in acquired renal cystic disease. *A*, Unenhanced CT scan shows multiple bilateral fluid-density cysts with cyst wall calcifications. An area (arrow) located medially in the right kidney was considered suspicious for a neoplasm. *B*, T1-weighted (TR = 500 msec, TE = 15 msec) spin-echo MR image shows that most cysts have low signal intensity. However, two lesions (arrows) located medially in the right kidney have a high signal intensity, which persisted on T2-weighted images (not shown), findings consistent with cyst hemorrhage.

Figure 41-45. Acquired renal cystic disease and a right perinephric hematoma (arrows) in a patient undergoing long-term dialysis. (From Levine E, Grantham JJ, Slusher SL, et al: CT of acquired cystic kidney disease and renal tumors in long-term dialysis patients. *AJR Am J Roentgenol* 142:125-131, 1984.)

Figure 41-46. Acquired renal cystic disease and metastatic renal cell carcinoma in a 46-year-old man treated with hemodialysis for 120 months. *A*, Contrast-enhanced CT scan shows multiple bilateral renal cysts and nephromegaly. The enlarged left renal hilar lymph node (*arrow*) is due to a metastasis. *B*, A caudal CT scan reveals two solid, heterogeneous masses (*arrows*) with irregular contours and focal calcifications in the lower pole of the left kidney. The masses enhanced by 30 HU. (From Levine E, Slusher SL, Grantham JJ, Wetzel LH: Natural history of acquired renal cystic disease in dialysis patients: A prospective longitudinal CT study. *AJR Am J Roentgenol* 156:501–506, 1991.)

Figure 41-47. Growth of renal cell carcinoma in a patient with acquired renal cystic disease who was undergoing hemodialysis. *A*, The first CT scan shows a small mass (*arrow*) in the upper pole of the left kidney. *B*, A CT scan performed 18 months later during an episode of gross hematuria reveals that the left renal mass (*arrows*) has enlarged and become heterogeneous, suggesting renal cell carcinoma. On pathologic examination, the lesion had invaded the renal capsule. Linear strands related to the right kidney resulted from perinephric hemorrhage. (From Levine E, Grantham JJ, MacDougall ML: Spontaneous subcapsular and perinephric hemorrhage in end-stage kidney disease: Clinical and CT findings. *AJR Am J Roentgenol* 148:755–758, 1987.)

Figure 41-48. Multiple renal cysts in two different patients with von Hippel-Lindau disease. *A*, Contrast-enhanced CT scan shows multiple bilateral renal cysts. *B*, T2-weighted (TR = 2200 msec, TE = 90 msec) spin-echo MR image shows multiple cysts with high signal intensities involving both kidneys.

Figure 41-49. Growth of a renal cell carcinoma in a patient with von Hippel-Lindau disease. The right kidney was previously resected because of renal cell carcinoma. The patient refused surgery for the left renal lesion until after the third CT scan. *A*, There is a 1.8-cm solid mass (arrow) in the lower pole of the left kidney. *B*, A follow-up CT scan obtained 2 years after *A* shows that the lesion (arrow) had enlarged to 2.2 cm as well as mild heterogeneity. *C*, A CT scan obtained 3 years after *B* shows that the lesion has now replaced most of the left kidney. A left nephrectomy was performed, and hemodialysis was started.

Hereditary Syndromes

Von Hippel-Lindau Disease

It is estimated that approximately 7000 patients in the United States have von Hippel-Lindau disease (VHLD). The incidence of VHLD is approximately 1 in 40,000 live births. The disease, inherited as an autosomal dominant trait with high penetrance, is caused by a genetic defect in the short arm of chromosome 3.²⁴⁹ Manifestations of VHLD include retinal angiomas, central nervous system hemangioblastomas, pancreatic cysts, islet cell tumors, pheochromocytomas, endolymphatic sac tumors, cystadenomas of the epididymis, and broad ligament and renal cysts and tumors.³⁵ The abdominal lesions are best detected on CT.^{37,38} VHLD that is not associated with pheochromocytoma is subclassified as VHLD1 and VHLD that is associated with pheochromocytoma as VHLD2. Multiple bilateral renal cysts and cystic and solid neoplasms are the most common manifestation of VHLD (Fig. 41-48). Most cysts remain stable with long-term CT follow-up and transformation from typical simple cysts to solid lesions is rare.^{35,37} However, complex lesions with both cystic and solid elements may transform into solid lesions and therefore require careful imaging follow-up.³⁷

RCC is reported to develop in 24% to 45% of patients with VHLD and is often multifocal and bilateral.^{164,165} VHLD-associated renal cysts are lined by hyperplastic epithelium that is commonly intermixed with foci of tumor.²⁰⁷

Figure 41-50. Multiple pancreatic cysts with mild pancreatic enlargement in von Hippel-Lindau disease.

Figure 41-51. Right adrenal pheochromocytoma (arrow) in von Hippel-Lindau disease.

Once solid renal lesions develop, they grow at rates similar to those of sporadic RCCs (Fig. 41-49).³⁷ Predominantly cystic lesions with solid components are characteristic of VHL. The solid component usually represents RCC.²⁰⁷

The pancreas is commonly involved in VHL, with pancreatic cysts occurring in about 30% of patients (Fig. 41-50). Solid pancreatic lesions, including nonfunctional islet cell tumor and ductal carcinoma, occur less commonly in VHL. Pheochromocytomas, which occur in 10% of patients with VHL, are often multiple and ectopic; approximately 50% to 80% are bilateral (Fig. 41-51).^{148, 219}

Screening in families affected by VHL permits timely genetic counseling and early identification of potentially life-threatening lesions. Abdominal CT should first be performed late in the second decade in at-risk individuals (i.e., primary relatives of patients with the diagnosis). The frequency of imaging thereafter depends on the initial findings. Patients with suspicious renal lesions may require annual CT evaluation.

Tuberous Sclerosis Complex

Tuberous sclerosis complex (TSC) may be inherited as an autosomal dominant trait or may occur sporadically. Tuberous sclerosis is an autosomal dominant disorder often associated with a chromosome 9 (TSC1) and chromosome 16 (TSC2) abnormality, although up to 60% of cases occur spontaneously. The incidence of the disorder is between 1 in 10,000 and 100,000 live births, and it leads to multiple organ and skeletal abnormalities.^{35, 70} The classic triad of epilepsy, mental retardation, and adenoma sebaceum defines the syndrome clinically.⁷⁰ Renal lesions, seen in 50% of patients with TSC, include multiple cysts, angiomyolipomas (AMLs), tumors and perirenal cystic collections, or lymphangiomas.^{35, 303} Other associated abnormalities are subependymal nodule, giant cell astrocytoma, peripheral tubers, retinal hamartoma, cardiac rhabdomyoma, lymphangioleiomyomatosis, shagreen patch, subungual fibroma, and bone cyst.³⁵ Multiple renal AMLs are the sine qua non of TSC and are usually bilateral; they occur in about 15% of patients, mostly females.³⁰³ The AMLs are benign renal tumors composed of fat, smooth muscle, and abnormal blood vessels. Abnormal vessels (aneurysmal dilatations) predispose the lesions to hemorrhage. The rate of hemorrhage within TSC-related AMLs is higher than that found in sporadic AMLs.³⁵

CT scans usually demonstrate a large fatty mass intermixed with areas of tissue density that may represent nonfatty parts of the tumor or areas of hemorrhage (Fig. 41-52). The tumor commonly extends into the perinephric space and is often complicated by intratumoral or perinephric hemorrhage. CT is also useful in identifying perinephric extension and hemorrhage. The CT appearance of AMLs that are composed primarily of smooth muscle, or in which intratumoral hemorrhage has obscured the fatty part of the tumor, is indistinguishable from that of other solid renal tumors.²⁴³

Renal cystic disease in TSC may sometimes be the earliest and only clinical manifestation of the disorder in infancy and childhood.¹⁷⁸ The kidneys are often signifi-

Figure 41-52. Tuberous sclerosis with renal cystic disease in a 15-year-old female. *A*, Contrast-enhanced CT scan shows enlarged kidneys with multiple fluid-density cysts. The appearances closely resemble that of autosomal dominant polycystic kidney disease. *B*, Unenhanced CT scan shows a 1.9-cm rounded lesion (arrowhead) in the left kidney with a fat attenuation value of 110 HU. The findings indicate an angiomyolipoma and strongly suggest tuberous sclerosis. (From Mitnick JS, Bosniak MA, Hilton S, et al: Cystic renal disease in tuberous sclerosis. *Radiology* 147:85-87, 1983.)

Figure 41-53. Tuberous sclerosis with renal cystic disease in a 14-year-old female. *A*, Unenhanced CT scan displays kidneys containing multiple cysts. No fat-containing angiomyolipomas were detected. *B*, A cranial CT scan reveals paraventricular calcifications (arrows), indicating diagnosis of tuberous sclerosis and permitting differentiation from autosomal dominant polycystic kidney disease.

cantly enlarged in such patients and are replaced by multiple cysts of varying size (see Fig. 41-52). The cysts involve the renal cortex and medulla, and the findings are similar to those of ADPKD.¹⁷⁴ The cysts in TSC are not a diagnostic feature, occurring at an earlier age than in ADPKD.

The combination of renal cysts and AMLs is strongly suggestive of tuberous sclerosis.¹⁷⁴ If no renal AMLs are found in a patient suspected of having TSC, cranial CT may help establish the diagnosis of TSC by showing small, high-attenuation periventricular subependymal nodules (Fig. 41-53).²⁶⁹

Renal Lymphangiectasia

Renal lymphangiectasia is probably due to developmental obstruction of the larger lymphatics draining the

kidney through the renal pedicle.^{21, 156, 200} The condition is usually bilateral and is characterized on imaging studies by large lymphatic cysts in the renal sinuses, perinephric tissues, and central retroperitoneum, as well as diffuse intrarenal lymphangiectasia (Fig. 41-54).^{180, 214} Renal lymphangiectasia is usually discovered clinically because of abdominal masses due to nephromegaly. The disorder may be complicated during pregnancy by large perinephric lymph collections and ascites (Fig. 41-55).¹⁷¹ These findings may be secondary to lymphatic rupture due to increased renal lymph flow during pregnancy in the presence of lymphatic obstruction.¹⁷¹

Figure 41-54. Renal lymphangiectasia in a 10-month-old boy with abdominal masses on routine physical examination and normal renal function. A contrast-enhanced CT scan reveals nephromegaly and many renal sinus, perinephric, and central retroperitoneal lymphatic cysts. (From Blumhagen JD, Wood BJ, Rosenbaum M: Sonographic evaluation of abdominal lymphangiomas in children. *J Ultrasound Med* 6:487-495, 1987.)

Figure 41-55. Renal lymphangiectasia in a 25-year-old woman who experienced severe abdominal distention during pregnancy. An unenhanced CT scan shows large bilateral perinephric lymph collections and renal sinus lymphatic cysts. (From Meredith WT, Levine E, Ahlstrom NG, Grantham JJ: Exacerbation of familial renal lymphangiomas during pregnancy. *AJR Am J Roentgenol* 151:965-966, 1988.)

Renal Parenchymal Neoplasms

Malignant renal parenchymal neoplasms may be either primary or secondary. RCC is the most common primary renal cancer, accounting for about 86% of all primary malignant renal parenchymal neoplasms. Of the remainder, 12% are Wilms' tumors and 2% are renal sarcomas.¹⁴² Secondary neoplasms of the renal parenchyma include malignant lymphoma and metastases. The most common renal neoplasm overall, is metastases.²⁰³

Renal Cell Carcinoma

RCC is a common urologic malignant lesion in adults and accounts for 2% of all cancers. It may occur at any age, although most patients are more than 40 years, and persons in the seventh and eighth decades of life are most commonly affected.²⁰⁹ In children over 5 years, only 0.3% to 1.3% of all cases of RCC present in childhood.⁸⁶ Known risk factors are cigarette smoking, exposure to petroleum products, obesity, ACRD, VHL, TSC, and hereditary papillary renal cancer.^{179, 209}

Current imaging techniques have had a notable effect on tumor detection. Kidney cancers are being diagnosed at an earlier stage and with greater precision.¹⁶⁶ Small early-stage carcinomas are now commonly identified during abdominal CT or ultrasonography performed for nonrenal complaints (Fig. 41-56).¹⁵¹ Indeed, almost as many new RCCs are currently being detected incidentally as are being found in patients investigated because of hematuria or flank pain.

CT Technique and Imaging

Scanning protocol for RCC consists of a combination of unenhanced (or CT imaging) in the corticomedullary and nephrographic phases. The corticomedullary phase (25 to 70 seconds from the start of injection of contrast material) is best for evaluating venous extension of RCC. The nephrographic phase (80 to 180 seconds after the start of injection) is best for evaluating the renal mass.²⁴⁴

Single-detector and multidetector spiral CT allows rapid image acquisition through the entire kidney in single breath-hold during various phases of contrast enhancement after the administration of a single bolus of intravenous contrast material.²⁴⁴ CT is the primary modality for the detection, diagnosis, and staging of RCC. The precontrast CT appearance of RCC varies considerably, depending on the gross pathologic features. Neoplasms may be hypodense, isodense (see Fig. 41-56), or hyperdense (Fig. 41-57) compared with normal renal parenchyma on unenhanced CT scans.³⁰⁰ Most RCCs are solid lesions with attenuation values of 20 HU or greater on unenhanced CT.²⁴⁸ Tumor calcification occurs in as many as 31% of cases and may take the form of amorphous internal calcification (Figs. 41-57 and 41-58) or curvilinear calcification (Fig. 41-59), which may be peripheral or central.³⁰⁰

After administration of intravenous contrast medium, most RCCs enhance, but usually to a lesser extent than normal renal parenchyma (see Figs. 41-56 and 41-57). This feature is best seen in nephrographic phase,^{17, 265} the most important phase for detecting renal masses.²⁴⁴ Enhancement is often heterogeneous because of tumor hemorrhage or necrosis (see Figs. 41-57 and 41-58).¹⁴² The mass often shows an indistinct interface with the surrounding parenchyma and frequently has a lobulated or irregular outer margin. Small RCCs, however, often have distinct, smooth margins.^{242, 300}

MRI assumes a primary role in tumor detection and staging in patients in whom contrast-enhanced CT scanning is contraindicated because of either previous major reactions to contrast material or renal failure.^{64, 223} MRI may be used as a supplement to CT in patients who have renal carcinoma and venous tumor extension and in whom the status of the vena cava is not clearly established.^{64, 69, 91}

The usual appearance of RCC on MR imaging is that of a lesion which is hypointense to isointense to renal parenchyma on T1-weighted images, heterogeneously hyperintense on T2-weighted images and demonstrates less enhancement than renal parenchyma after administration of gadolinium. The appearance can vary, however, depending on tumor histology, the presence or absence of intratumoral

Figure 41-56. Renal cell carcinoma. A, The neoplasm (arrows) has a similar density to normal renal parenchyma on an unenhanced CT scan. B, A contrast-enhanced CT scan shows a homogeneous 2.3-cm mass (white arrows) with a slightly irregular outline. The attenuation value increased from 37 to 87 HU. A small renal cyst (black arrow) is seen anteriorly.

Figure 41-57. Renal cell carcinoma. *A*, Small (2.9-cm) renal mass (*arrow*) has a higher density than normal renal parenchyma on an unenhanced CT scan. *B*, A precontrast CT scan through the upper part of the lesion shows a small-focus of amorphous calcification (*arrow*). *C*, Nephrographic phase CT scan shows that the mass (*arrow*) enhances less than normal renal parenchyma and reveals low-density areas due to tumor necrosis. The mass has an indistinct interface with adjacent renal parenchyma.

lipid, hemorrhage, and necrosis.^{209, 245} RCC may be hyperintense, hypointense, or isointense to normal renal parenchyma on both T1- and T2-weighted images. The use of intravenous gadolinium enhancement with fat suppression on T1-weighted imaging makes tumors much more conspicuous.^{240, 241} Solid RCCs often show contrast enhancement and may reveal irregular, ill-defined margins and

heterogeneity (Fig. 41-60). Tumor calcification is difficult to appreciate on MRI.

Staging of Renal Cell Carcinoma

The prognosis of patients with RCC depends mainly on histologic tumor grade and the anatomic extent or stage of the disease when first seen. RCC is most commonly staged according to the system proposed by Robson and colleagues²²¹; alternatively, the TNM classification may be used (Table 41-1). In the Robson system, stage I RCC consists of tumor confined within the renal capsule, stage II of perinephric extension, including the ipsilateral adrenal

Figure 41-58. Renal cell carcinoma. Small foci of amorphous calcification (*arrowheads*) are present in a left renal carcinoma. The mass has an indistinct interface with adjacent renal parenchyma, and it is heterogeneous.

Figure 41-59. Renal cell carcinoma. Left renal carcinoma (*arrows*) shows peripheral curvilinear calcification. The right kidney is small because of renal artery stenosis.

Figure 41-60. Gadolinium-enhanced MR image of renal cell carcinoma. Coronal (T1-weighted and fat-suppressed sequence with gadolinium) image in the nephrographic phase demonstrates a mass that enhances less than the adjoining renal parenchyma in the midpole of the right kidney.

gland, stage IIIA of venous invasion (renal vein that may extend into the inferior vena cava), stage IIIB of regional lymph node metastases, and stage IIIC of both venous tumor extension and regional lymph node metastases. Stage IVA neoplasms extend through the Gerota's fascia to involve adjacent organs, and stage IVB neoplasms have distant metastases.

Radiologic staging of RCC has an important influence on management. Small stage I neoplasms (<3 cm) are managed by partial nephrectomy in many institutions (Fig. 41-61).²⁰⁹ A radical nephrectomy is usually required for stage II tumors. The operation includes removal of the kidney, adrenal gland, perirenal fat, and Gerota's fascia with or without a regional lymph node dissection.¹⁹⁹ Lymphadenectomy is commonly employed, but its effectiveness has not been definitively proved. Stage III tumors are also managed with radical nephrectomy with extension of surgery to remove the entire renal vein and caval thrombus and a portion of the vena cava as necessary.¹⁰¹ Preoperative detection of venous tumor thrombus is important, because the surgical approach changes according to the cephalad extent of the tumor extension into the inferior vena cava.¹⁹⁰ Treatment of stage IV RCC differs from center to center. Almost all cases are incurable. Tumor embolization, external-beam irradiation, and nephrectomy can aid in the palliation of symptoms due to the primary tumor or to related ectopic hormone production. The main chemotherapeutic agents in use are interleukin-2 and interferon alfa.^{189, 288}

CT is the single most effective modality for staging RCC, with an overall accuracy of about 90%.^{10, 61} CT and MRI achieve approximately equal accuracy in the local staging of RCC.¹⁰ Perinephric invasion is suggested by a perinephric soft tissue mass at least 1 cm in diameter (Fig. 41-62), but lesser degrees of perinephric involvement are difficult to diagnose with CT (Fig. 41-63).^{111, 133} Perinephric soft-tissue stranding is an unreliable indicator of perinephric tumor invasion. Venous tumor invasion can be

Table 41-1. Staging Systems for Renal Cell Carcinoma and Their CT Criteria

Tumor Position	Robson Stage	TNM Class	CT Findings	CT Pitfalls
Confined within renal capsule	I	...	Soft tissue mass enhances less than normal renal parenchyma; central necrosis in large renal cell carcinoma	...
Small (<7 cm diameter)	...	T1
Large (≥7 cm diameter)	...	T2
Spread to perinephric fat	II	T3a	Perinephric stranding; perinephric collateral vessels	Not reliable or specific; found in 50% of T1 and T2 tumors; false-negative if spread is microscopic
Venous thrombus	IIIA	...	Soft tissue mass in perinephric space Filling defect within a distended vein; direct continuity of thrombus with primary mass; IV contrast enhancement indicates tumor thrombus; collateral veins	Specific, not sensitive in 45%–50% of cases False-negative: right renal vein and IVC obscured by large renal cell carcinoma; false-negative: enhancing thrombus obscured; false-positive: venous enlargement due to increased flow; false-positive: streaming of unopacified blood in IVC (perform delayed scanning)
Renal vein only	...	T3b
IVC infradiaphragmatic	...	T3c
IVC supradiaphragmatic	...	T4b
Regional lymph node metastases	IIIB	N1–N3	Lymph nodes 1 cm in diameter or larger	False-negative rate: 4%; false-positive: enlarged inflammatory nodes
Direct invasion of adjacent organs	IVA	T4a	Obliteration of normal soft tissue planes between tumor and adjacent organs	False-positive: partial volume averaging; false-positive: tumor adherent but not directly invading
Distant metastases	IVB	M1a–d	Metastases enhance with IV contrast material; hepatic metastases best in arterial phase	Hypervascular metastases may be obscured in portal venous phase
	...	N4

IV = intravenous; IVC = inferior vena cava.

Figure 41-61. Renal cell carcinoma. *A*, Corticomedullary phase demonstrates a small exophytic mass in the midpole of the left kidney, isodense to the renal cortex (*arrow*). *B*, The nephrographic phase demonstrates that the mass (*arrowhead*) enhances less than the renal parenchyma. The patient underwent partial nephrectomy.

definitely diagnosed on CT only if there is identifiable thrombus in the renal vein (Figs. 41-64 and 41-65) or inferior vena cava (see Fig. 41-65) with or without venous enlargement.³⁰² Ipsilateral renal vein enlargement on CT without identifiable tumor thrombus is not a reliable sign of venous tumor extension (Fig. 41-66). Although such enlargement may reflect the presence of tumor thrombus, it more frequently results from increased blood flow due to a hypervascular tumor (see Fig. 41-66).³⁰² Errors in diagnosis of venous tumor extension on CT often occur when large right-sided tumors cause notable distortion of the ipsilateral renal vein and inferior vena cava.^{111, 152} Tumor thrombus is distinguished from a bland thrombus by the former's heterogeneous enhancement on corticomedullary phase and continuity with the primary tumor.^{244, 298}

MRI is superior in detecting venous tumor involvement and its extent and is a suitable alternative when CT findings

Figure 41-63. Renal cell carcinoma with early perinephric extension. Unenhanced fat-suppressed T1-weighted MR image (TR = 600 msec, TE = 15 msec) shows a large neoplasm (*straight arrows*) in the lower pole of the right kidney. There are early extension into the perinephric fat (*open arrow*) and associated renal fascial thickening (*curved arrows*).

Figure 41-62. Renal cell carcinoma. A right-sided tumor has invaded the perinephric fat posteriorly (*arrow*) and medially (*black arrowhead*). The medial perinephric mass indents the inferior vena cava. The renal fascia (*white arrowhead*) is thickened.

Figure 41-64. Left renal cell carcinoma with venous extension. The proximal part of the left renal vein is enlarged (*arrowheads*) and is occupied by low-density tumor.

Figure 41-65. Renal cell carcinoma with venous extension and regional lymph node metastases. *A*, Contrast-enhanced CT scan shows a right renal mass (black arrow). The right renal vein (white arrow) is enlarged and occupied by tumor, which has also extended into the inferior vena cava. There is a metastasis in the right lobe of the liver. *B*, Multiple enlarged, central retroperitoneal lymph nodes (arrows) were due to metastatic disease.

are indeterminate (see Figs. 41-66 and 41-67). Tumor thrombus in the renal vein and vena cava may be suspected on T1- and T2-weighted conventional imaging if the signal void of flowing blood is replaced by relatively high signal which is due to tumor thrombus (Fig. 41-68). Tumor thrombus has signal intensity similar to that of the primary neoplasm (see Fig. 41-68). Gradient-echo images are also useful for detecting venous tumor extension.^{78, 225} On such images, flowing blood has significantly increased signal intensity and appears white, whereas tumor thrombus has medium signal intensity and appears as an intravenous filling defect (Fig. 41-69).^{78, 225} MR angiographic 2D or 3D gradient-echo sequences with gadolinium enhancement are most widely used. The 3D slab is centered over the renal vessels in coronal plane.²⁰⁹ Sagittal or coronal MRI accurately evaluates the superior extent of vena caval thrombus relative to the diaphragm, hepatic veins, and right atrium.^{91, 225} The sensitivity of MRI has been reported at 90% for detection of inferior vena caval thrombus, compared with 79% for CT (Fig. 41-70).¹¹⁵

Regional lymph nodes are considered to be involved by tumor if they are at least 1 cm in diameter in the short axis. However, lymph nodes may be 1 to 2 cm in diameter because of reactive hyperplasia.¹¹¹ Lymph nodes larger than 2 cm in size are usually due to metastases (see Fig. 41-65).^{111, 152} Adjacent organ invasion is diagnosed only if there is enlargement, density change, or both, of an adjacent structure (Fig. 41-71). The loss of a fat plane between the tumor and an adjacent organ is not reliable evidence of tumor invasion (see Fig. 41-71).¹¹¹ RCC most commonly metastasizes to the lungs and mediastinum, bones, and liver (see Fig. 41-65). Less common sites are the adrenal glands, kidney, brain, pancreas, mesentery, and abdominal

Postnephrectomy Evaluation. Recurrence of neoplasm in the renal bed occurs in about 5% of patients after radical nephrectomy, as detected on follow-up CT. Patients with large, invasive tumors have a higher risk of local recurrence than those with small, early-stage tumors.⁸⁹ Renal bed recurrence is most likely within 2 years of nephrectomy.²⁹⁰ The liver, ascending colon, second part of duode-

Figure 41-66. Left renal cell carcinoma with renal vein enlargement (arrow) on contrast-enhanced CT scan (*A*). The right kidney is atrophic. On MRI (*B*) (spin-echo, TR = 2100 msec, TE = 30 msec), the left renal vein (arrows) is enlarged but shows a normal signal void, indicating that venous enlargement is probably due to increased blood flow rather than tumor extension. The inferior vena cava (open arrow) is also normal.

Figure 41-67. Significant retrocaval extension of renal cell carcinoma with extrinsic caval invasion. The relationship of the cava to the tumor was not adequately determined by CT. **A**, Sagittal unenhanced MR image (spin-echo, TR = 500 msec, TE = 15 msec) shows retrocaval tumor extension with anterior caval displacement (*open arrow*). **B**, MR image (spin-echo, TR = 500 msec, TE = 15 msec) performed after IV gadolinium-DTPA administration reveals marked tumor enhancement (*arrow*). The vena cava (*open arrow*) is displaced anteriorly and compressed. **C**, More cephalad MR image shows extrinsic caval tumor invasion (*arrow*) near the level of entry of the hepatic veins.

num, pancreatic head, and small bowel migrate into the right renal fossa; the pancreatic tail, spleen, and large and small bowel migrate into the left renal fossa. Interpretational errors can be avoided in patients who have undergone nephrectomy by ensuring adequate bowel opacification with oral contrast medium. Postoperative scarring in the renal fossa is distinguished from neoplasm recurrence if the area shows no change on serial CT examinations.⁴

Local recurrence of neoplasms may also be suggested by enlargement or irregularity of the psoas muscle on the side of the nephrectomy (Fig. 41-72), although this finding may also be caused by postoperative scarring.¹⁵ In all patients undergoing radical nephrectomy or partial nephrectomy for RCC, a baseline postoperative CT scan of the abdomen should be obtained, and CT scanning should be performed at regular intervals thereafter.

Partial Nephrectomy

Nephron-sparing surgery is the treatment of choice when radical nephrectomy would render the anephric patient with a subsequent need for dialysis.²⁴⁴ Current accepted indications for nephron-sparing surgery are (1) RCC in a solitary functioning kidney, (2) RCC in a patient with compromised renal function, and (3) multiple bilateral tumors, which are common in VHL and hereditary RCC.^{209, 244} The most suitable lesion for nephron-sparing nephrectomy is smaller than 4 cm, polar, cortical, and far from the renal hilum and collecting system.²⁴⁴

Renal Medullary Carcinoma

Renal medullary carcinoma is a rare tumor of the kidney, first described by Davis and colleagues in 1995.⁵⁵ This tumor occurs exclusively in young black patients with sickle cell trait (HbSA and HbSC) but not sickle cell anemia.^{32, 55} Affected patients range from 11 to 39 years in age.⁵⁵ Flank pain and hematuria are the most common presenting complaints.²⁸⁶ The exact histologic origin of this tumor is controversial. It has been suggested that renal medullary carcinoma represents a particular aggressive form of collecting duct carcinoma.²⁵⁶ Metastatic involvement of regional lymph nodes, liver, and lungs at presentation is common.¹²⁹

Renal medullary carcinoma is thought to arise at the renal pelvis-mucosa interface. The tumor quickly grows to fill the renal pelvis and invade vascular and lymphatic structures. Intraparenchymal satellite nodules are frequently present.¹⁶⁰

The radiologic appearance of renal medullary carcinoma is that of a prototypical infiltrative lesion. An ill-defined mass centered in the renal medulla with extension into the renal sinus and cortex is characteristic; caliectasis may be seen, and the reniform contour of the kidney is maintained (Fig. 41-73).²⁰³ The tumors are heterogeneous on ultrasonography and contrast-enhanced CT, reflecting the characteristic tumor necrosis.⁵¹ The prognosis is extremely poor, with advanced disease at the time of diagnosis. The tumor responds poorly to chemotherapy or radiation therapy, with

Figure 41-68. Inferior vena caval extension of right renal cell carcinoma. A, Unenhanced MR image (spin-echo, TR = 500 msec, TE = 17 msec) shows neoplasm extension into the right renal vein (black arrow) and the inferior vena cava (white arrow). The venous tumor has a signal intensity similar to that of the primary neoplasm. B, More cephalad MR image shows intracaval tumor (arrow) at the level where the three hepatic veins join the cava. C, Sagittal MR image shows intracaval tumor (black arrows). The supradiaphragmatic part of the cava (white arrow) is not affected.

Figure 41-69. Inferior vena caval extension of left renal cell carcinoma. A gradient-echo MR image (TR = 60 msec, TE = 12 msec, flip angle = 60°) shows tumor extension along the left renal vein (arrow) and into the inferior vena cava. Flowing blood in the cava appears white and the tumor is shown as a filling defect (arrowhead). (Courtesy of Richard L. Ehman, M.D., Rochester, Minn.)

Figure 41-70. MR image obtained after gadolinium enhancement, in the same patient shown in Figure 41-62, demonstrates enlarged renal vein with enhancement (arrow). At surgery, the enlargement was confirmed to be tumor extension into the renal vein.

Figure 41-71. Left renal cell carcinoma with extension beyond the renal fascia. *A*, The tumor invades the abdominal wall in the region of the left quadratus lumborum muscle (*arrow*). Tumor has grown along a needle biopsy track in the subcutaneous tissues (*arrowhead*). Tumor invasion of the descending colon (*open arrow*) was confirmed at surgery. Although the neoplasm abuts the left psoas muscle, there was no actual muscle invasion. *B*, Contrast-enhanced MR image (spin-echo, TR = 500 msec, TE = 15 msec) reveals that the neoplasm does not invade the psoas muscle (*p*). However, tumor has invaded the abdominal wall (*long arrow*) and the colon (*short arrow*).

Figure 41-72. Local recurrence of renal cell carcinoma 7 years after nephrectomy for right renal cell carcinoma. Patient presented with upper gastrointestinal bleeding. *A*, An enhancing mass (*curved arrow*) causes enlargement of the right psoas muscle. The third part of the duodenum (*straight arrow*) and the inferior vena cava (*arrowhead*) are adherent to the mass. *B*, MRI (spin-echo, TR = 500 msec, TE = 15 msec) performed after IV injection of gadolinium-DTPA shows an enhancing mass (*arrow*) involving the right psoas muscle. Endoscopy with biopsy showed clear cell carcinoma invading the third part of the duodenum (*open arrow*).

Figure 41-73. Medullary carcinoma. Transverse oblique view (*A*) of right kidney shows an upper pole hyperechoic mass. (*B*) Contrast-enhanced axial CT shows heterogeneous enhancement of mass. (Courtesy of Pickhardt PJ: Abdominal Imaging, 1998.)

a mean survival of 15 weeks from diagnosis. The constellation of renal medullary mass, black race, sickle cell trait, and hemoglobin SC disease suggests the diagnosis.¹⁶⁰

Collecting Duct Carcinoma

Collecting duct carcinoma (Bellini duct carcinoma), originating from the collecting ducts of the kidney accounts for only 1% of renal carcinomas.¹¹⁸ The age at presentation ranges from 16 to 62 years with median age of 43 years.⁶⁰ Hematuria is the most common presentation and most patients have metastases at presentation.^{60, 169} Collecting duct tumors demonstrate aggressive behavior; a maximum survival of approximately 2 years is reported.^{60, 124, 169}

CT demonstrates renal medullary involvement with an infiltrative appearance and renal sinus encroachment. The reniform contour of the kidney is preserved except when an expansile component is present (Fig. 41–74). Collecting duct carcinomas are hypointense on T2-weighted images and hypovascular on angiography.^{201–203}

Wilms' Tumor. Wilms' tumor accounts for 87% of pediatric renal neoplasms.^{114, 220} Approximately 80% of children with this tumor present between 1 and 5 years of age, with the peak incidence between 3 and 4 years.³¹ Occasional cases are encountered during adult life.⁷⁹ Most patients present because of an enlarging abdominal mass.¹⁰⁴ Less common presenting symptoms include abdominal pain, fever, and microscopic or gross hematuria.⁸⁶ The lung

Figure 41–74. Collecting duct carcinoma. *A*, Sagittal view of right kidney shows a hyperechoic mass in the upper pole. *B*, Axial contrast-enhanced CT scan demonstrates low-attenuating right renal mass that abuts the renal sinus. Axial T1-weighted image (*C*) and coronal T2-weighted image (*D*) reveal the mass to be isointense to renal parenchyma on T1-weighted and hypointense on T2-weighted sequences relative to the renal parenchyma. (From Pickhardt PJ, Lonergan GJ, Davis CJ, et al: From the Archives of the AFIP: Infiltrative renal lesions: Radiologic-pathologic correlation. Radiographics 20:215–243, 2000.)

is the most frequent site of metastatic disease, and the liver is less frequently involved.

With appropriate therapy about 95% of patients with Wilms' tumor can be cured.²⁹¹ Tumor histology and stage are the most useful predictors of patient outcome and help determine the nature of therapy. Although all Wilms' tumors require surgical resection, preoperative imaging helps determine tumor stage and resectability, therefore influencing decisions about preoperative chemotherapy or radiation therapy.^{47, 291} Ultrasonography is the most common method for initial diagnosis of Wilms' tumor. However, CT and MRI have been found to be more accurate than ultrasonography in tumor staging.^{47, 246} Chest and abdominal CT may be performed during the same examination, thereby determining the presence or absence of lung metastases.⁸⁶

On CT, a Wilms' tumor usually appears as a large, spherical, intrarenal mass, very often with a well-defined rim of compressed renal parenchyma or pseudocapsule surrounding it (Fig. 41-75). Tumors that arise in the peripheral cortex may grow in an exophytic manner with most of the tumor mass outside the kidney.⁷⁹ The tumor is less dense than normal renal parenchyma on contrast-enhanced CT scans; areas of low attenuation coincide with tumor necrosis, fat deposition, or both (Fig. 41-76).⁸⁶ About 13% of Wilms' tumors contain calcifications as seen on unenhanced CT scans.^{79, 86} About 10% of patients show poor or absent function of the involved kidney because of either venous tumor extension, compression of the collecting system, or extensive tumor infiltration throughout the kidney.

Perinephric tumor extension thickens the renal fascia and obliterates the perinephric fat, but subtle perinephric extension may be missed on CT. Central retroperitoneal adenopathy may be detected on CT, although the distinction between nodes enlarged as a result of metastases and those enlarged because of reactive changes is usually not possible.^{47, 246} Renal vein and inferior vena caval tumor extension is best shown after an intravenous bolus injection of contrast medium. The thrombus may be seen as a low-density intraluminal filling defect. CT may also identify bilateral Wilms' tumors (Fig. 41-77), present in about 10% of patients,¹⁶⁰ and liver and pulmonary metastases.^{47, 216}

Figure 41-75. A large heterogeneous Wilms' tumor is present in the left kidney. The residual renal parenchyma is displaced medially (arrows).

Figure 41-76. Wilms' tumor of left kidney with extensive necrosis. A contrast-enhanced CT scan shows that the tumor has a mainly fluid density. Solid and enhancing tumor elements are present medially (arrows).

On MRI, Wilms' tumor appears as a large, well-defined mass with relatively distinct margins (Fig. 41-78). It has low signal intensity on T1-weighted images and high signal intensity on T2-weighted images.¹⁶⁰ The tumor often appears heterogeneous on both T1- and T2-weighted images. Although MRI is sensitive for detecting regional lymph node enlargement, it cannot predict the cause of the enlargement.²⁴⁶ Currently, CT and MRI appear equivalent for staging Wilms' tumor. However, MRI shows venous extension better than CT (see Fig. 41-78).²⁴⁶

Nephroblastomatosis. Nephrogenesis is normally complete by 34 to 35 weeks of gestation. However, metanephric blastema may persist into infancy and childhood. Foci of persistent metanephric tissue are designated as nephrogenic "rests." The presence of multiple nephrogenic rests is termed *nephroblastomatosis*. There is wide acceptance of nephroblastomatosis as a precursor lesion to Wilms' tumor. Thirty percent to 34% of Wilms' tumors arise from these

Figure 41-77. Multicentric and bilateral Wilms' tumors. The tumors have a low density, and they compress residual enhancing renal tissue.

Figure 41-78. Wilms' tumor of right kidney shown by MRI (spin-echo, TR = 600 msec, TE = 15 msec). *A*, An axial image reveals that the mass is well defined and displaces normal renal tissue (arrow) posteriorly. *B*, A coronal image shows that the mass indents the inferior vena cava (arrows), but does not extend to the vena cava.

rests. Approximately 35% of patients with diffuse nephroblastomatosis eventually have Wilms tumor.¹⁵⁹ Hyperplastic nephrogenic rests are macroscopic and plaque-like (Fig. 41-79). Any macroscopic nephrogenic rest that is nodular and enlarges over time is considered neoplastic.²⁸⁹ Nephroblastomatosis occurs most often in neonates and is characterized by multiple-bilateral subcapsular masses.¹⁶⁰

CT is the technique of choice for detection of this disorder. On contrast-enhanced CT, in addition to nephromegaly, the kidney may show striate enhancement. The rests enhance less than adjacent normal parenchyma.²⁰³ CT is particularly useful for evaluating the other kidney in the child with Wilms' tumor, for renal screening in children with syndromes associated with Wilms' tumor, and for follow-up evaluation for neoplastic changes in patients with known nephroblastomatosis.^{75, 289} The hallmark of neoplastic transformation of a benign nephrogenic rest is enlargement on serial CT scans.²⁸⁹

On MRI, nephroblastomatosis tends to be hypointense to renal cortex on T1-weighted images and isointense to

cortex on T2-weighted images.⁹⁵ Gadolinium enhancement adds to the conspicuity of these lesions, although contrast-enhanced studies have not been found superior to unenhanced studies for lesion detection.⁸⁶

Renal Sarcoma. Primary renal sarcomas are rare (accounting for approximately 1% of malignant renal parenchymal tumors) mesenchymal tumors that generally have a poor prognosis. Subtypes of renal sarcoma include leiomyosarcoma, angiosarcoma, hemangiopericytoma, liposarcoma, rhabdomyosarcoma, fibrosarcoma, and osteosarcoma. The biologic behavior of the various types of sarcoma is highly variable.^{203, 257} Leiomyosarcoma is the most common renal sarcoma, accounting for about 58% of all sarcomas.⁷¹ Hemangiopericytoma and liposarcoma each account for about 20% of renal sarcomas.⁷¹ Renal rhabdomyosarcoma and osteogenic sarcoma occur rarely. Capsular localization, a feature of more than 50% of these tumors,⁷¹ should suggest the diagnosis on CT (Figs. 41-80 and 41-

Figure 41-79. A hyperplastic intralobar nephrogenic rest presents as a low-density subcapsular mass (arrow) on a contrast-enhanced CT scan.

Figure 41-80. Undifferentiated liposarcoma (arrows) arising in the perinephric fat. The neoplasm is confined within the renal fascia (arrowheads). The left kidney is displaced laterally, but the tumor has not invaded the renal parenchyma.

Figure 41-81. A and B, Renal osteosarcoma. A densely ossified mass (arrows) arises peripherally in the lower pole of the right kidney. (Courtesy of Clive Levine, M.D., Columbia, Mo.)

81). When these neoplasms arise in the renal parenchyma, however, they are indistinguishable from RCC on CT.

Renal liposarcomas usually arise in the renal capsule or perinephric fat (see Fig. 41-80).⁷¹ On CT, liposarcomas cause compression without invasion of the renal parenchyma and show a variety of appearances correlating closely with their gross and histologic features.¹³⁷ Tumors containing a large amount of mature fat show negative attenuation values. Myxoid liposarcomas contain little mature fat, and their predominantly fluid and connective tissue composition results in attenuation values nearer those of water.¹³⁷ On CT, undifferentiated liposarcomas are indistinguishable from other types of sarcoma (see Fig. 41-80). The diagnosis of renal osteogenic sarcoma is suggested on CT by a peripherally located renal mass containing dense ossification (see Fig. 41-81).²⁹⁷

Renal Lymphoma

Renal involvement by lymphoma is usually secondary to systemic disease, because the kidney does not contain lymphoid tissue.^{40, 203, 276} However, secondary renal involvement occurs commonly either from generalized hematoge-

nous dissemination of lymphoma or by direct extension of retroperitoneal disease.⁴⁰ Bilateral renal involvement occurs more frequently, being present in 75% of all patients with lymphoma. Renal involvement occurs significantly more commonly in non-Hodgkin's lymphoma than in Hodgkin's disease.²⁷⁶ Five CT patterns of renal lymphoma are as follows: 1) multiple renal masses, 2) solitary mass, 3) renal invasion from contiguous retroperitoneal disease, 4) perirenal disease, and 5) diffuse renal infiltration.²⁷⁶

With the extensive use of abdominal CT for lymphoma staging, renal lymphoma is now recognized on CT in about 8% of patients with lymphoma.⁴⁰ Multiple renal nodules are the most common CT manifestation of renal lymphoma, occurring in about 59% of cases (Fig. 41-82).^{40, 217} The nodules range from 1 to 3 cm, are less dense than normal renal parenchyma on contrast-enhanced CT scans, and typically show a homogeneous appearance. As multiple renal nodules grow, coalesce, and replace nephrons, the kidneys are almost diffusely replaced by lymphoma (Fig. 41-83). However, the multinodular nature of the disease process usually remains apparent. In most patients, the renal arteries and veins remain patent despite tumor encasement, a finding that is characteristic for lymphoma.²⁷⁶ Retroperitoneal lymph node enlargement is not visible on CT in a significant percentage of patients with renal lymphoma that

Figure 41-82. Non-Hodgkin's lymphoma with bilateral multiple renal masses. There is extensive retroperitoneal adenopathy (arrowheads).

Figure 41-83. Bilateral renal replacement and mild nephromegaly in non-Hodgkin's lymphoma. There is no enlargement of retroperitoneal lymph nodes.

Figure 41-84. Renal involvement from retroperitoneal non-Hodgkin's lymphoma. There is extensive central retroperitoneal adenopathy causing lateral displacement of the kidneys. The upper pole of the left kidney (arrow) is invaded through the renal capsule. Tumor extends into the right kidney via the renal sinus (arrowhead).

is not due to direct spread of retroperitoneal tumor (see Fig. 41-83).^{40, 217}

Renal involvement from retroperitoneal lymphoma commonly occurs either by invasion through the renal capsule or by extension through the renal sinus (Fig. 41-84). This pattern accounts for about 28% of patients with renal lymphoma. Retroperitoneal adenopathy is invariably present, and many patients show obstructive hydronephrosis. Rarely, a solitary mass in one kidney is the only CT manifestation of renal lymphoma (about 3% of cases) (Fig. 41-85). Some patients (about 10%) show a predominance of perinephric disease without extensive parenchymal or retroperitoneal disease (Fig. 41-86).

On MRI, renal lymphoma tends to be hypointense relative to the renal cortex on T1-weighted images and heterogeneously hypointense or isointense on T2-weighted images. Minimal enhancement is generally detected, although renal lymphoma enhances considerably less than normal renal parenchyma. MRI characteristics of treated lymphoma are variable.^{40, 209}

Figure 41-85. Hodgkin's disease with solitary heterogeneous left renal mass.

Figure 41-86. Right perinephric mass (arrowheads) shown on unenhanced CT scan in a patient with non-Hodgkin's lymphoma. A large nodal mass (arrow) involves the small bowel mesentery.

Metastases

The frequency of metastases to the kidney in patients with cancer is 7% to 13% in large autopsy series.^{30, 196} The kidney is the fifth most common site of metastases in the body, after lung, liver, bone, and adrenals; most metastases reach the kidney via the hematogenous route.¹⁷⁵ The three neoplasms with the highest frequency of renal metastases are lung carcinoma, breast carcinoma, and carcinoma of the other kidney.

Renal metastases are usually discovered incidentally during abdominal CT performed for tumor staging. However, some patients have hematuria and flank pain.¹⁷⁵ The most common pattern on CT is that of multiple discrete bilateral lesions. Solitary exophytic metastases are more common in patients with colon cancer, and perinephric tumor extension is typical of melanoma (Fig. 41-87).³⁶ These lesions are best seen on contrast-enhanced CT scans.

Figure 41-87. Renal metastases from colonic carcinoma. Axial contrast-enhanced CT scan shows a low-attenuating mass with minimal enhancement in the inferior pole of right kidney (arrow). Multiple low-attenuating lesions are also seen in the liver, which are metastases from colonic carcinoma.

Figure 41-88. Left renal metastasis (arrow) and retrocrural adenopathy (arrowhead) in a patient with small cell lung cancer. A follow-up scan after 3 weeks of chemotherapy showed complete resolution of the renal mass and adenopathy.

Although metastases are usually homogeneous on CT, larger lesions may show central necrosis.¹⁷⁵ Occasionally, patients with metastases have solitary renal masses.³⁶ If the patient has other areas of metastatic disease and a current known primary neoplasm, such solitary renal lesions can usually be safely assumed to be metastases, and pathologic proof of their nature is unnecessary (Fig. 41-88).^{36, 175} However, in the patient with no other metastases, it is difficult to determine whether the renal lesion is a synchronous RCC or a renal metastasis (Fig. 41-89). In these circumstances, further investigation is necessary, particularly if there has been an apparent remission of the primary neoplasm. Tissue sampling is usually necessary in such cases.

Benign Neoplasms

Adenoma. During the last decade, there has been a significant increase in detection of asymptomatic renal tumors 3 cm or less in diameter by sonography and CT (Fig. 41-90).^{151, 283} Most such tumors are neoplasms of tubular origin. In the past, such lesions were often classified as renal adenomas, because they rarely metastasize. However,

Figure 41-89. Solitary renal metastasis from squamous cell carcinoma of the lung. The patient underwent a left upper lobectomy. Two years later, he demonstrated left flank pain and hematuria. CT scan shows a heterogeneous left renal mass (arrow). No other lesions were found. A renal cell carcinoma was suspected, but percutaneous biopsy revealed metastatic squamous carcinoma.

Figure 41-90. Small (1.8-cm) renal cell carcinoma (arrow) detected incidentally by CT.

serial imaging shows that they often gradually enlarge (Fig. 41-91)¹⁹ and that even small tumors may metastasize (Fig. 41-92).²⁵⁴ Indeed, such lesions are histologically indistinguishable from larger carcinomas more commonly encountered in the kidneys, and they often have histologic grades indicating a definite potential for malignant behavior. Accordingly, most investigators believe that these lesions should be regarded as carcinomas in an early stage of evolution and should not be classified as adenomas.^{19, 151} On CT, these small renal tumors are usually well-defined and homogeneous in appearance (see Fig. 41-90).^{151, 254} Less commonly, they show marginal irregularity, heterogeneity, or central calcification (see Fig. 41-57), findings that may suggest pathologically high-grade tumors.²⁶ These lesions are best managed with partial nephrectomy^{262, 278} provided that the other kidney is normal.

Oncocytoma. The renal oncocytoma is a solid epithelial neoplasm with a generally benign course.⁵⁷ It represents between 10% and 15% of small (<3 cm) solid renal neoplasms.²²³ They arise from proximal tubular epithelium (oncocyte) and range in size from 1.5 to 13 cm with a mean of 6.3 cm.¹⁰⁶

On CT, oncocytomas typically are well-defined masses with smooth, rounded margins (Fig. 41-93).⁵³ Tumor calcification occurs rarely, and oncocytomas are sometimes multiple and bilateral.^{46, 109} Small oncocytomas are usually homogeneous in appearance on contrast-enhanced CT scans, although they are occasionally heterogeneous because of the presence of central scars (Fig. 41-94). On CT, small oncocytomas are usually indistinguishable from slowly growing small RCCs that lack hemorrhage or necrosis.⁵³ A central, sharply defined stellate scar (Fig. 41-95) is present in 25% to 33% of large oncocytomas and strongly suggests the diagnosis.²¹³

The classic angiographic findings for the oncocytoma are a spoke-wheel pattern, a homogeneous nephrogram, and a sharp, smooth rim. The finding of a homogeneous blush or a spoke-wheel pattern greatly increases the possibility of an oncocytoma, though an RCC may have any or all of the classic findings described for an oncocytoma.²⁸⁷ However, CT criteria are usually poor discriminants for distinguishing between oncocytoma and RCC, regardless

Figure 41-91. Progression of renal cell carcinoma shown by serial CT in a 70-year-old man who underwent bladder carcinoma resection 6 years previously. The patient initially refused surgery. *A*, Contrast-enhanced CT scan shows a 2.5-cm renal mass (arrow). *B*, Follow-up scan obtained 3 years later shows that the mass (arrow) has enlarged to 3.8 cm. *C*, Unenhanced CT scan obtained 2 years after *B* shows further enlargement of the mass (arrow), which measures 6.5 cm.

Figure 41-92. Small renal cell carcinoma with sacral metastasis. The patient was a 42-year-old man who complained of low back pain. *A*, A lytic metastasis (arrowhead) is present in the right sacral ala. *B*, CT performed to search for a primary neoplasm shows a small mass (arrow) with dense peripheral calcification in the left kidney. Histologic examination revealed a high-grade left renal cell carcinoma.

Figure 41-93. Left renal oncocytoma. A contrast-enhanced CT scan shows a homogeneously enhancing, well-circumscribed, exophytic renal mass (arrow).

Figure 41-94. Left renal oncocytoma (arrow) with eccentric scar (arrowhead). Distinction from a small renal cell carcinoma is not possible on CT.

Figure 41-95. Large left renal oncocytoma (arrow). The centrally placed, sharply defined, stellate area of low attenuation (arrowheads) suggests the diagnosis of oncocytoma.

of tumor size.⁵³ Fine-needle aspiration cytology has been shown to be successful in discriminating between RCC and renal oncocytoma.¹⁵⁷ If the diagnosis of oncocytoma is suspected preoperatively, small tumors may be treated with partial nephrectomy because of the excellent prognosis.²¹⁰ On MRI, oncocytoma is generally isointense to hypointense to normal parenchyma on T1-weighted images and has a variable appearance on T2-weighted images. The presence of a central scar suggests the diagnoses (Fig. 41-96). Oncocytomas do enhance with gadolinium administration but less than renal parenchyma.

Juxtaglomerular Neoplasm (Reninoma).¹⁸⁵ Renin-producing tumors of juxtaglomerular cells (reninomas) are a rare,⁶⁵ but curable, cause of hypertension. Two thirds of juxtaglomerular cell tumors of the kidney occur in young women in their reproductive years.¹⁰⁴ Plasma renin and aldosterone values are usually elevated. None of the reported neoplasms has been invasive or has metastasized. Reninomas are usually well shown on contrast-enhanced CT scans on which they show a smooth outline and sharp margination. Small foci of hemorrhage may cause a heterogeneous tumor appearance. Because of their benign nature, reninomas may be managed by partial nephrectomy.¹⁸⁵

On MRI, reninomas are isointense to hypointense to normal cortex on T1-weighted images and hypointense to normal cortex on T2-weighted images. These tumors tend to enhance less than normal cortex on MRI because of their relative hypovascularity.^{1, 117, 209}

Multilocular Cystic Renal Tumor. Multilocular cystic renal tumor (MCRT) refers to two types of generally benign tumors: cystic nephroma (CN) and cystic poorly differentiated nephroblastoma (CPDN).¹¹³ These are well-encapsulated, multilocular, noninfiltrating cystic lesions with no solid components. MCRT manifests in young children (usually boys) as a painless abdominal mass. Affected females usually are over 4 and the tumor demonstrates a biphasic age distribution, occurring in girls 4 to 20 years of age and in women in their fifth and sixth decades of life.¹⁶³ The masses are often large, averaging 8 to 10 cm in diameter, are single, are unilateral, and involve only part of the kidney. Individual cysts may vary from microscopic to 2 to 4 cm.¹⁸⁶ CPDN resembles CN in every feature on histopathology and imaging examinations, except that the septa contain blastemal cells with or without other embryonal stromal cells.

On CT, MCRT presents as a well-defined encapsulated mass containing multiple cysts separated by septa (Fig. 41-97). The septa may be as thick as several millimeters, but they do not display significant nodularity. On contrast-enhanced CT, septa within the mass may enhance.¹⁶³ Excretion of contrast by the affected kidney is usually normal. However, the lesion frequently herniates into the renal pelvis causing a filling defect and, sometimes, obstructive calycectasis (Fig. 41-98).¹⁶³ MRI does not add much information to that provided by CT (see Fig. 41-98). MRI shows encapsulated multilocular mass with capsule that has low signal on all pulse sequences, variable signal intensity of cyst contents on T1-weighted images, and high signal intensity of cyst contents on T2-weighted images.⁸⁶ CN and CPDN are indistinguishable by imaging or by

Figure 41-96. A 78-year-old woman with oncocytoma. A, Coronal T1-weighted MR image shows a mass in the inferior pole of right kidney; the mass is slightly hyperintense to the renal parenchyma. B, T2-weighted fast spin-echo image shows mass to be hyperintense to the surrounding renal parenchyma with a high signal central scar. Precontrast T1-weighted axial fast multiplanar spoiled gradient image (C) shows mass to be slightly hyperintense to the renal parenchyma with low signal central scar, which demonstrates enhancement on post-gadolinium enhancement sequences (D).

Figure 41-97. Multilocular cystic nephroma (white arrow) in the right kidney in an infant. Multiple septa separate the fluid-containing locules. The renal parenchyma is displaced medially and posteriorly (black arrows).

Figure 41-98. Multi-locular cystic nephroma occurring in the right kidney in an infant. *A*, CT scan shows fine septa in well-defined cystic renal mass (arrow). Hydronephrosis (open arrow) was due to herniation of the tumor into the right renal pelvis. *B*, Coronal MR image (spin-echo, TR = 350 msec, TE = 15 msec) obtained posteriorly through the right kidney shows dilated calyces (white arrows) and renal pelvis (curved arrow). *C*, Coronal T1-weighted MR image (spin-echo, TR = 350 msec, TE = 15 msec) shows that the tumor has a heterogeneous appearance with area of high signal intensity probably due to hemorrhage or high protein content in cyst fluid. *D*, Axial proton-density-weighted MR image (TR = 2000 msec, TE = 22 msec) shows that fluid locules have significantly variable signal intensities.

Figure 41-99. Small renal angiomyolipoma. *A*, Unenhanced CT scan shows a low-density mass (arrow) in the lower pole of the left kidney. Attenuation values as low as -42 HU, indicating the presence of fat, were found in the lesion through the use of small regions of interest. *B*, On a contrast-enhanced CT scan, the attenuation values of the lesion (arrow) were in the soft tissue range.

Figure 41-100. Tuberous sclerosis with multiple bilateral renal angiomyolipomas. The lesions contain low-density areas consistent with fat.

gross appearance. The treatment for MCRT is complete resection, with noninvasive imaging for follow-up if the tumor proves to be CPDN.⁸⁶

Angiomyolipoma. AMLs are benign hamartomas composed of blood vessels, smooth muscle, and fatty tissue. AML is seen in two distinct clinical forms, sporadic (isolated) and in association with tuberous sclerosis. Although exact figures are difficult to obtain, the sporadic form accounts for approximately 80% to 90% of cases of AML.²⁸² The sporadic form is typically seen in middle-aged patients (mean age, 43 years) and is more common in women by at least a 4:1 ratio. Up to 80% of all patients with TSC, including adults and children, have AMLs.⁸⁶ When found in children, AMLs are almost exclusively associated with TSC.⁸⁶ Masses less than 4 cm in diameter are usually asymptomatic, but those larger than 4 cm often cause flank pain, hematuria, and anemia and carry a significant risk of intratumoral or perinephric hemorrhage.^{260, 279}

AMLs are seen on CT as well-circumscribed renal masses. They vary in size from tiny renal nodules to large tumors (Fig. 41-99). Patients with TSC often have extensive bilateral renal involvement by AMLs (Fig. 41-100). The presence of intratumoral fat is almost diagnostic

of AMLs,²⁹ although in rare cases, fat has been reported in Wilms' tumor in children¹⁹⁵ and in renal oncocytomas.⁴⁶ Retroperitoneal lymph node involvement may be discovered in patients with AML.²⁶⁷

The presence of fat is best shown by CT. Thin-section (3 to 5 mm) technique is preferred to avoid volume averaging, which might prevent demonstration of low attenuation in the tumor. The use of intravenously administered contrast material is not necessary (see Fig. 41-99).²⁸² Fatty tissue is considered to be present in a tumor if a region-of-interest attenuation measurement of -10 HU or lower is found within the tumor. Lesions without detectable fat cannot be distinguished from other renal neoplasms on CT (Fig. 41-101). Approximately 5% of AMLs do not show fat attenuation on CT scans and cannot be differentiated from RCC.²⁸² Extensive intratumoral hemorrhage may also obscure the presence of fat. AMLs are always benign. However, the tumors may exhibit extrarenal extension. Large perinephric tumor components may be found (Fig. 41-102), and AMLs may extend into the renal vein and inferior vena cava.⁸⁶

MRI may also detect the presence of fat in renal AMLs (Fig. 41-103). The MRI characteristics of AML depend on the relative amounts of fat and other tissue components. The presence of macroscopic fat in a lesion is very specific for AML, although rarely, RCC can also contain fat.¹⁰³ If an AML is suspected on chemical shift imaging, the diagnosis can be confirmed by acquiring fat-saturated, T1-weighted and water-saturated, T1-weighted gradient-echo sequences.²⁰⁹

Surgery and biopsy are rarely needed in asymptomatic patients with typical imaging findings of AML. Patients with extensive intratumoral or perinephric hemorrhage can usually be managed conservatively (Fig. 41-104). Partial nephrectomy or selective catheter embolization is advocated for masses larger than 4 cm.^{125, 279} Generally, asymptomatic patients with an AML approaching 4 cm in diameter are followed annually with CT or ultrasonography although in most of these patients the lesions will show

Figure 41-101. Two left renal angiomyolipomas in a patient without tuberous sclerosis. A, A lesion (curved arrow) in the upper pole of the left kidney contains fat, indicating the diagnosis of angiomyolipoma. B, A mass (arrow) in the midregion of the kidney contained no detectable fat and was therefore indistinguishable from a renal cell carcinoma. Nephrectomy revealed that both lesions were angiomyolipomas, although the lesion shown in B had only a minimal fat content.

Figure 41-102. Tuberous sclerosis with renal and liver involvement. *A*, The kidneys show multiple fat-containing lesions. On the right side, there is extensive involvement of the perinephric space by an angiomyolipoma (arrows) containing fat and prominent blood vessels. The right kidney is displaced anteromedially. *B*, A fat-containing mass (arrow) is present in the left lobe of the liver. (Courtesy of Randi W. Hart, M.D., Waukesha, Wis.)

Figure 41-103. Multiple angiomyolipoma. In- and out-of-phase MR image in axial projection (*A*) demonstrates multiple small lesions in the right kidney that have a slightly higher signal compared with the surrounding renal parenchyma. *B*, Out-of-phase pulse sequence demonstrates a significant drop in the signal of these lesions, consistent with the presence of fat. Post-gadolinium enhancement images (not shown) did not reveal any enhancement.

Figure 41-104. Extensive left perinephric hematoma due to hemorrhage from a renal angiomyolipoma. *A*, The hematoma (arrows) is partially contained by the posterior renorenal bridging septum. *B*, A more cephalad scan shows a fat-containing angiomyolipoma (arrows) closely related to the hematoma. The bleeding responded to conservative management.

little change over time. Patients with lesions larger than 4 cm can be evaluated at shorter intervals.²⁸²

Pelvicalyceal and Ureteral Neoplasms

Primary neoplasms of the renal pelvis, calyces, and ureter are relatively uncommon. CT plays a limited but often important role in the diagnosis and staging of these tumors.

Pelvicalyceal Neoplasms

About 90% of pelvicalyceal cancers are transitional cell carcinomas, about 9% are squamous cell carcinomas, and less than 1% are adenocarcinomas.^{93, 138} Occupational exposure to industrial dyes, phenacetin abuse, cigarette smoking, prior cyclophosphamide therapy, and urinary stasis associated with horseshoe kidneys predispose an individual to the development of transitional cell carcinoma.^{138, 143} Squamous cell carcinoma of the renal pelvis is commonly associated with chronic irritation secondary to renal calculi and chronic infection. Transitional cell carcinoma has a peak frequency in the sixth and seventh decades of life, and about 68% of affected patients are men. Patients present with painless hematuria.¹⁸⁶ Transitional cell carcinoma of the renal pelvis is frequently multicentric with either synchronous or metachronous tumor involvement of the ureter, bladder, and contralateral renal pelvis.^{186, 293}

CT Diagnosis

Imaging findings in urothelial cancer consist of a calyceal or renal pelvic filling defect, hydronephrosis with a nonfunctioning kidney, and extensive renal parenchymal infiltration.¹³⁸ The diagnosis of pelvicalyceal cancer is usually established by various combinations of excretory urography, retrograde pyelography, retrograde brush biopsy, ureteroscopy, and biopsy. CT helps in establishing the extent of renal parenchymal invasion including the perinephric and periureteral extents of tumor.

CT evaluation of pelvicalyceal filling defects of unknown nature shown by excretory urography or retrograde pyelography requires unenhanced, corticomedullary, nephrographic, and excretory-phase images through the abdomen and pelvis using a slice thickness of 3 to 5 mm. Small pelvicalyceal neoplasms may be difficult to detect on precontrast scans, although occasional neoplasms show coarse, punctate calcification.⁶² Contrast-enhanced CT demonstrates collecting system filling defects with smooth, lobulated, or irregular margins (Fig. 41-105).⁸ Precontrast attenuation values of pelvicalyceal cancers range from 20 to 46 HU.¹⁹⁴ Although characteristically hypovascular on angiography, pelvicalyceal tumors often show mild enhancement on CT after intravenous administration of contrast medium. Postcontrast attenuation values range from 64 to 84 HU.¹⁹⁴ Contrast enhancement differentiates pelvicalyceal neoplasms from other filling defects that occur in the collecting system.

Radiolucent renal calculi are usually composed predom-

Figure 41-105. Polypoid transitional cell carcinoma (arrow) of the right renal pelvis. The lesion invaded to but not beyond the muscularis. Compared with the unenhanced CT scan, the lesion enhanced on this scan by 36 HU.

inantly of uric acid and appear as densities with attenuation values greater than 200 HU on unenhanced CT scans (Fig. 41-106).^{73, 239} The attenuation values of recent pelvicalyceal blood clots on unenhanced CT scans range from 45 to 75 HU; these values are higher than those of urothelial cancer and lower than those of urate calculi.¹³⁸ Moreover, blood clots do not have contrast enhancement and follow-up studies show disappearance of blood clots with time.¹³⁸ CT enables the recognition that an apparent intrinsic pelvic filling defect is produced by extrinsic compression of the renal pelvis by renal sinus lipomatosis, renal sinus cysts, RCCs, and lymphoma.

The hydronephrotic form of urothelial cancer with a nonfunctioning kidney is due to ureteropelvic junction obstruction and may present a diagnostic problem on excretory urography.¹³⁸ Although retrograde pyelography may suggest the diagnosis, CT sometimes provides a definitive diagnosis (Fig. 35-107).²³⁷ An enhancing soft-tissue mass

Figure 41-106. Urate calculus (arrow) in the left renal pelvis. Excretory urography showed a pelvic filling defect, but the lesion was radiolucent on conventional tomography. The stone has an attenuation value of 458 HU.

Figure 41-107. Hydronephrosis due to transitional cell carcinoma of the right renal pelvis. *A*, A soft-tissue mass (arrow) fills the right renal pelvis. Dilated calyces (arrowheads) are seen in the right kidney. An enlarged retrocaval lymph node (open arrow) was involved by metastatic disease. *B*, The tumor also involved the upper half of the right ureter (arrow).

Figure 41-108. Congenital ureteropelvic junction obstruction. *A*, Longitudinal sonogram of left kidney shows marked hydronephrosis with medial tapering of the renal pelvis. *B*, Corresponding CT scan reveals the medial tapering of the renal pelvis and marked hydronephrosis. The ureter beyond the junction was collapsed. The patient underwent pyeloplasty.

at the apex of a dilated renal pelvis or diffuse thickening of the renal pelvic wall on CT indicates a tumor causing ureteropelvic junction obstruction. The proximal ureter may be thickened and filled from invasion by the neoplasm (see Fig. 41-107).¹³⁸ Most cases of ureteropelvic junction obstruction are congenital in origin, and on CT, a dilated renal pelvis with a smooth wall and a smooth transition at the ureteropelvic junction to the collapsed proximal ureter is seen (Fig. 41-108).²³⁷ A calculus impacted at the ureteropelvic junction is easily shown by CT (Fig. 41-109). Extrinsic lesions causing ureteropelvic junction obstruction (e.g., enlarged lymph nodes or retroperitoneal neoplasms) are also easily diagnosed on CT.²³⁷

Another presentation of urothelial cancer is that of extensive parenchymal infiltration of the kidney.²⁰³ Urothelial cancer is centrally located, and its pattern of renal invasion differs from the eccentric origin and invasion of the renal sinus seen in RCC. Urothelial cancers do not usually distort the shape of the kidney. The demonstration of a central mass that is less dense than normal renal parenchyma and

Figure 41-109. Axial CT scan demonstrates a large right ureteropelvic junction calculus.

Figure 41-110. Transitional cell carcinoma of the right renal pelvis in a 20-year-old man associated with cyclophosphamide therapy administered 6 years earlier. *A*, Dynamic CT scan obtained immediately after bolus injection of contrast material shows an enhancing mass (arrowheads; attenuation value = 71 HU) in the right renal pelvis. The precontrast attenuation value was 43 HU. The mass obliterates and invades the renal sinus fat. A poorly defined margin between the tumor and the renal parenchyma indicates parenchymal invasion. *B*, A CT scan obtained 5 minutes after *A* shows displacement of the opacified collecting system. (From Levine E: Transitional cell carcinoma of the renal pelvis associated with cyclophosphamide therapy. *AJR Am J Roentgenol* 159:1027-1028, 1992.)

shows minimal tumor enhancement strongly suggests a urothelial cancer (Fig. 41-110).¹³⁸ The renal sinus fat may be obliterated, and there is often a poorly defined margin between the tumor and the renal parenchyma.¹³⁸ The calyces may be displaced, compressed, or dilated.

Tumor Staging

Conservative therapy is considered an option in patients with a solitary functioning kidney, bilateral tumor, and renal insufficiency. However, nephroureterectomy with excision of a bladder cuff is considered the standard treatment and should be performed whenever possible.¹⁰² When conservative surgery is planned, CT is helpful for tumor staging.¹⁷³ Patients with high-grade or high-volume pelvic-lyceal cancers have a high frequency of metastases, primarily to regional lymph nodes, lung, bones, and liver in decreasing order of frequency.

Although CT cannot demonstrate the depth of tumor invasion in the renal pelvic wall (see Fig. 41-105), it can

show whether the tumor has extended beyond the tunica muscularis into the renal sinus fat.⁸ Invasion of renal sinus fat is suggested by obliteration of the peripelvic fat stripe, which is the renal sinus fat separating the anterior and posterior cortical hilar lips from the renal pelvic adventitia (see Fig. 41-110).⁸ Invasive renal pelvic tumors may become attached to the aorta and inferior vena cava and may invade the psoas muscle (Fig. 41-111). In rare cases, tumor extension into the renal vein and inferior vena cava may be shown by CT.⁸⁵ CT may also demonstrate regional lymph node metastases (Fig. 41-112), although the technique sometimes leads to “understaging” of tumors with metastases in normal-sized central retroperitoneal lymph nodes.⁸ MRI is not used frequently in the diagnosis and management of urothelial tumors. However, it may help determine local extent of tumor.

Ureteral Neoplasms

Transitional cell carcinoma accounts for about 93% of ureteral neoplasms. Of the remainder, 5% are squamous cell carcinomas, and 2% are adenocarcinomas. The age and gender distribution, symptoms, and causes are similar to those for pelvic-lyceal carcinoma. Tumors have a predi-

Figure 41-111. Invasive transitional cell carcinoma of the left renal pelvis. The tumor (T) causes left hydronephrosis. It extends through the wall of the renal pelvis and is attached to the aorta (a) and the left psoas muscle (arrowhead). Complete resection was not possible.

Figure 41-112. Transitional cell carcinoma of the right renal pelvis with extensive parenchymal invasion and regional nodal metastases (arrows).

Figure 41-113. Transitional cell carcinoma of the left ureter. The patient presented with hematuria, and on excretory urography, the left kidney did not excrete contrast medium. **A**, Unenhanced CT scan reveals left hydronephrosis. **B**, Caudal scan shows dilated left ureter (arrow) filled with fluid-density urine. **C**, Scan at the level of the aortic bifurcation shows that the ureter contains a filling defect (arrow) with soft tissue density. The tumor is separated from the left psoas muscle (P) and the left common iliac artery (open arrow) by intact fat planes.

lection for the middle and distal ureter. The diagnosis of ureteral carcinoma is usually readily established with a combination of excretory urography and retrograde pyelography. However, CT may help by confirming that a ureteric filling defect represents a neoplasm and not a radiolucent calculus or blood clot. Ureteral neoplasms manifest on CT as soft tissue intraluminal filling defects (Fig. 41-113), often with ureteral widening or thickening of the ureteral wall.

These findings can also occur in inflammatory conditions and ureteral metastases.¹³⁸ CT also helps determine whether a ureteral neoplasm has extended outside the tunica muscularis to involve the retroperitoneal fat (see Fig. 41-113) and surrounding structures, or whether it has metastasized to regional lymph nodes.

An important use of CT is to determine whether ureteral obstruction is due to an intrinsic neoplasm or to extrinsic disease when excretory urography and retrograde pyelography have failed to do so.²⁸ CT is particularly useful in detecting such causes of extrinsic ureteric obstruction as idiopathic and malignant retroperitoneal fibrosis, inflammatory aortic aneurysm, and lymphomatous and metastatic retroperitoneal adenopathy.²⁸

Renal Infections

Acute Bacterial Renal Infection

Acute bacterial renal infection in adults frequently causes fever, chills, flank pain, leukocytosis, and pyuria. It occurs significantly more commonly in women. Vesicoureteric reflux is sometimes an important predisposing factor in children, but it is only rarely found in adults with acute pyelonephritis. *Escherichia coli* bacteria usually cause the typical ascending acute renal infection, whereas the hema-

togenous disease is often caused by *Staphylococcus aureus*.¹⁹¹ The diagnosis of acute bacterial renal infection is usually made clinically, and about 95% of patients with uncomplicated infections treated with appropriate antibiotics become afebrile in 48 hours, and nearly 100% do so in 72 hours.²⁵⁵ Such patients do not need renal imaging. However, imaging studies are valuable in patients with severe refractory renal infections. Imaging is needed to determine if there are complications requiring prolonged antibiotic therapy or surgical intervention (e.g., renal and perinephric abscess or pyonephrosis). Imaging is also useful for excluding abnormalities that predispose to refractory infections, such as nephrolithiasis or ureteric obstruction.

Acute Bacterial Pyelonephritis. In patients with acute bacterial renal infection, CT scans are acquired with contrast enhancement during the corticomedullary phase (30 seconds after initiation of injection and during either the nephrographic phase (70–90 seconds after injection) or the excretory phase (5 minutes after injection).²⁷⁷ A striated nephrogram on contrast-enhanced CT that consists of discrete rays of alternating attenuation extending to the cortex is characteristic of pyelonephritis and is better demonstrated on CT than on excretory urography.²⁰³ Striations result from stasis of contrast material within edematous tubules that demonstrates increasing attenuation over time.²⁷⁷ Some patients with acute pyelonephritis show diffuse renal involvement on CT. This is manifested by poor renal contrast enhancement, delay to absence of excretion of contrast medium, and global renal enlargement (Fig. 41-114). Other patients show unifocal or multifocal renal abnormalities with extensive areas of apparently uninvolved renal parenchyma.⁹⁰ These abnormalities are seen on contrast-enhanced CT scans as wedge-shaped zones of decreased attenuation (Fig. 41-115). They often manifest

Figure 41-114. Acute pyelonephritis with diffuse renal involvement. The affected left kidney shows diminished contrast enhancement, global enlargement, and delayed contrast excretion. The right kidney is normal.

straight borders, radiate from the collecting system to the renal capsule, and are widest at the periphery of the kidney.^{90, 255, 270} Severe tubulo-interstitial inflammation may progress to form a hypodense mass or masses with rounded or irregular contours and bulging of the renal surface (Fig. 41-116). If treated too late or inadequately, such lesions may develop single or multiple small areas of liquefaction (i.e., small abscesses).⁹⁰ These areas are often irregular and of near water attenuation (20 to 30 HU); they do not enhance after intravenous administration of contrast medium (Fig. 41-117).

Renal and Perinephric Abscesses. If inadequately treated, acute pyelonephritis may progress to tissue necrosis, resulting in renal abscess. On contrast-enhanced CT scans, renal abscesses usually have attenuation values of about 30 HU; this feature distinguishes them from fluid-density renal cysts.²⁵⁵ Their contents do not enhance. They may have distinct, rounded margins and thick, enhancing walls (Figs. 41-118 and 41-119).^{141, 255} Alternatively, ab-

Figure 41-115. Acute pyelonephritis. The kidney shows a wedge-shaped zone (black arrow) of decreased attenuation. The lesion exhibits straight borders, radiates from the collecting system to the renal capsule, and is widest at the kidney periphery. There is inflammatory change in the adjacent perinephric fat and localized renal fascial thickening (white arrows). A similar but smaller zone of inflammation (open arrow) is present anteriorly.

Figure 41-116. Acute pyelonephritis with focal mass formation. The kidney shows a rounded, heterogeneous mass (arrow) with a poorly defined margin. Inflammatory changes in the adjacent perinephric fat and renal fascial thickening (arrowheads) are also present.

Figure 41-117. Acute pyelonephritis with early abscess formation. The inflammatory mass (arrow) shows a small, peripheral area of liquefaction (arrowhead).

Figure 41-118. Right renal abscess (arrow) shows a thick wall and low density (30 HU). Inflammatory stranding is present in the perinephric fat.

Figure 41-119. Large right renal abscess. The lesion (arrow) has an attenuation value of 36 HU and shows a thick wall. High-density renal parenchyma on its anteromedial aspect (arrowhead) is probably due to retention of contrast medium in compressed and obstructed renal tubules on the periphery of the abscess.

cesses may be ill-defined and surrounded by zones of decreased parenchymal enhancement, representing inflammation that has not yet progressed to necrosis. Gas is occasionally found in renal abscesses.¹⁷⁷ Focal thickening of the adjacent renal fascia and stranding in the adjacent perinephric fat are common CT findings.¹⁴¹ A perinephric abscess may ultimately result if the infection extends through the renal capsule (Fig. 41-120). Although small renal abscesses may respond to antibiotic therapy alone, percutaneous drainage is usually the treatment of choice for larger renal abscesses. Perinephric abscesses always require drainage.¹⁷⁷ Abscesses can be drained with the use of CT or ultrasonographic guidance.

Emphysematous Pyelonephritis (EPN). Emphysematous pyelonephritis is a relatively uncommon life-threatening bacterial infection characterized by gas formation within the renal parenchyma or the perinephric space.¹⁹¹ Most patients with EPN are diabetic with an average age

Figure 41-120. Unenhanced CT scan shows a perinephric abscess (white arrow) complicating acute pyelonephritis in a diabetic patient. Gas collections (curved arrows) are present in the abscess, and the left kidney (arrowheads) is displaced anteriorly.

of 55 years. *E. coli* is the commonest bacteria found in patients with EPN; other bacteria found include *Klebsiella*, *Pseudomonas*, and *Proteus*. Two types of EPN have been defined. Type I is characterized by destruction of more than one third of the renal parenchyma with absence of fluid or fluid collection. A smaller gas collection may be present. Type II is characterized by either renal or perinephric fluid collection with bubbly or loculated gas or gas in the collecting system and destruction of less than one third of the renal parenchyma. Type I EPN has a mortality rate of 69%, and Type II a rate of 18%.²⁸⁴ CT is the most sensitive method for establishing the diagnosis and can also distinguish among gas in the collecting system, parenchymal gas, and gas in the perinephric tissues (Fig. 41-121).²²⁰ Gas in the renal pelvis or calyces is a benign entity and may be related to emphysematous pyelitis, representing gas-forming urinary tract infection that is associated with gas localized in only the renal collecting system (Fig. 41-122). Other causes of gas in the collecting system are ureteral instrumentation, a surgical or interventional radiologic procedure, and a fistulous connection with a hollow viscus.²²⁶

At present nephrectomy remains the primary therapeutic interventional modality for EPN, although CT-guided drainage appears to have good results in patients in whom surgery is contraindicated, or who have a solitary kidney, bilateral disease, or disease with renal or perinephric fluid collections.^{96, 222, 299}

Pyonephrosis. Pyonephrosis is the accumulation of pus in an obstructed pelvicalyceal system. It may appear when

Figure 41-121. Emphysematous pyelonephritis in a diabetic patient. There is extensive destruction of the right kidney (A and B), which is largely replaced by gas (white arrow). Gas is also present in the perinephric space (black arrows) (B). A right nephrectomy was performed.

Figure 41-122. Emphysematous pyelitis in a diabetic patient. Gas is present in both collecting systems (arrows), but the right kidney is more significantly involved. The renal parenchyma is uninvolved, and the infection responded to antibiotic therapy.

urinary tract infection occurs in patients with ureteric obstruction due to calculi, strictures, developmental ureteric anomalies, or malignant disease.¹⁹¹ Pyonephrosis is often associated with severe urosepsis. It represents a true urologic emergency requiring either urgent percutaneous nephrostomy or passage of a ureteral stent to bypass the obstruction (Fig. 41-123). The preferred examination is contrast-enhanced CT. On CT, patients with pyonephrosis may have increased pelvic wall thickness, inflammatory changes in the perinephric fat, and, in rare cases, layering of intravenously injected contrast material anterior to the pus in the dilated renal pelvis.^{81,295} Pelvicalyceal system gas in the absence of a history of urinary tract instrumentation, although uncommon, is a strong diagnostic indicator of pyonephrosis (Fig. 41-124).⁸¹ However, CT usually cannot reliably distinguish between infected and uninfected hydronephrosis (Fig. 41-123). The presence of both clinical signs of infection and hydronephrosis is an indicator more sensitive than CT findings of pyonephrosis. CT may show the site and cause of urinary tract obstruction (Fig. 41-123).¹⁹¹

Chronic Renal Infections

Xanthogranulomatous Pyelonephritis. Xanthogranulomatous pyelonephritis (XGP) is a chronic renal inflam-

Figure 41-124. Pyonephrosis complicating congenital uretero-pelvic junction obstruction in a diabetic patient. The significantly dilated right renal pelvis (arrows) shows a gas-fluid level, and gas is also present in dilated calyces (arrowheads).

matory disease associated with indolent bacterial infection. The inflammatory process begins in the renal pelvis and later extends into the medulla and cortex, which are gradually destroyed and replaced by lipid-laden macrophages (xanthoma cells).⁹² The disease is usually diffuse but may be focal. Patients are typically middle-aged women. Systemic symptoms include malaise, fever, chills, and weight loss. Nonspecific urinary symptoms include flank pain, increased frequency of micturition, dysuria, and nocturia. *E. coli* or *Proteus mirabilis* organisms are commonly cultured from the urine. CT is valuable in diagnosis and preoperative planning.⁹² Nephrectomy is usually required, particularly in the diffuse form of the disease.

On CT, findings of diffuse XGP are pathognomonic in most cases: diffuse reniform enlargement with ill-defined central low attenuation, apparent cortical thinning, staghorn calculus, and unilateral decrease or (more commonly) absence of renal excretion of contrast material (Fig. 41-125).^{9,203} Less commonly a small, contracted kidney with replacement lipomatosis is found (Fig. 41-126).⁹² A staghorn calculus is present in up to 70% of cases (see Fig. 41-126).²⁷² Multiple, fluid-density, rounded areas almost

Figure 41-123. CT Scans of pyonephrosis and severe urosepsis due to an obstructing left ureteric urate calculus not visible on plain films. A, There is decreased enhancement of the left renal parenchyma, and the left renal pelvis is dilated with delayed contrast excretion (arrow). B, An obstructing calculus (arrow) is present in the proximal ureter. Differentiation between simple hydronephrosis and pyonephrosis could not be made by CT. However, the diagnosis of pyonephrosis was suggested by clinical findings. The patient showed rapid response to percutaneous nephrostomy.

Figure 41-125. Xanthogranulomatous pyelonephritis. The right kidney is globally enlarged, shows no contrast excretion, and is replaced by multiple, rounded, fluid-density areas. A calculus (arrow) is present in a nondilated renal pelvis with a thickened wall. (Courtesy of David S. Hartman, M.D., Hershey, Pa.)

completely replace the renal parenchyma (see Fig. 41-125). Pathologically, these areas represent either dilated calyces or focal areas of parenchymal destruction filled with pus or debris. Histologically, these cavities are lined by xanthoma cells.⁹² Rim enhancement of the low-density areas often occurs. Extrarenal extension of the inflammatory process is common and may involve the perinephric space, pararenal spaces, ipsilateral psoas muscle, flank muscles, diaphragm, and skin (see Fig. 41-126).⁹² Perinephric and psoas muscle abscesses often occur. In the focal form of XGP, CT shows a poorly enhancing mass adjacent to a calyx or in one pole of a kidney. Associated calculi may be found. The focal form may be misdiagnosed as a renal neoplasm.¹²⁶

Malacoplakia. Malacoplakia is a rare inflammatory disease usually associated with chronic *E. coli* infection. The urinary collecting system (especially the bladder) is most frequently involved, but the renal pelvis, ureter, kidney, and other organs outside the genitourinary tract may be affected. Affected patients are usually middle-aged women with recurrent urinary tract infections.²⁶ Malacoplakia is attributed to abnormal macrophage response. The histologic hallmark of the disorder is the presence of basophilic inclusions, called *Michaelis-Gutmann bodies*, within large eosinophilic macrophages.⁶³ Renal parenchymal

Figure 41-127. Renal parenchymal malacoplakia. CT scan shows a nonspecific soft tissue mass (black arrow) extending from the left kidney and invading the perinephric space and the left flank (white arrow). (Courtesy of David S. Hartman, M.D., Hershey, Pa.)

mal malacoplakia is usually unilateral but can be bilateral. Contrast-enhanced CT demonstrates multiple poorly defined hypodense cortical masses and associated decreased excretion of the contrast material in cases with extensive parenchymal replacement.^{99, 275} Nephromegaly and perinephric extension of disease may occur.¹²⁶ The CT findings are nonspecific, and renal parenchymal malacoplakia may be indistinguishable from a neoplasm (Fig. 41-127).

Tuberculosis. Renal tuberculosis usually results from hematogenous dissemination of a pulmonary infection. The diagnosis is usually best made on excretory urography, which shows typical calyceal and ureteric abnormalities. CT may show a variety of abnormalities, many of which are nonspecific. Obstruction of a single major calyx or of a group of minor calyces often occurs because of scarring. The obstructed calyces are dilated and show no excretion of contrast medium, and thinning of the overlying renal parenchyma occurs.¹²⁶ Tuberculosis of the renal pelvis is manifested as either hydronephrosis secondary to ureteropelvic junction obstruction or diffuse pelvic contraction with fibrosis extending down a thickened ureter. The vari-

Figure 41-126. Xanthogranulomatous pyelonephritis with a contracted kidney. A, A staghorn calculus (arrow) is present in the right renal pelvis. The right kidney is small and replaced by oval, fluid-density areas. B, A more cephalad CT scan shows extensive chronic inflammatory change (arrows) in the posterior pararenal space.

Figure 41-128. Renal tuberculosis with diffuse parenchymal calcification involving most of the right kidney (*arrow*) as shown on an unenhanced CT scan. (Courtesy of David S. Hartman, M.D., Hershey, Pa.)

ous patterns of hydronephrosis seen at CT depend on the site of the stricture and include focal caliectasis, caliectasis without pelvic dilatation, and generalized hydronephrosis.²⁸⁵ Low-density parenchymal lesions, probably representing areas of caseous necrosis, may be seen.¹²⁶ The calcifications within the renal parenchyma may be amorphous, granular, curvilinear, or lobar (“putty kidney”) (Fig. 41-128).⁹⁷ In a tuberculous putty kidney, large, round or oval, dense renal calcifications representing calcified caseating material in medullary cavities and dilated calyces are found. This condition, also called tuberculous autonephrectomy, is due to the superimposition of ureteral obstruction on renal parenchymal tuberculosis (Fig. 41-129).

Renal Trauma

Renal trauma may be caused by both blunt and penetrating abdominal injuries. Blunt trauma is responsible for most renal injuries. Such injuries are usually mild and heal without specific therapy.¹⁶⁸ Serious renal injury is often associated with damage to other structures, such as the liver, spleen, bowel, pancreas, or chest. Multiorgan involvement occurs in about 80% of patients with penetrating injuries and in about 75% of those with blunt trauma.^{66, 231}

Figure 41-129. Renal tuberculosis. The left kidney shows large, oval, dense calcifications (*arrow*) representing calcified caseating material in medullary cavities and dilated calyces (tuberculous autonephrectomy). Low-density areas in the right kidney probably represent foci of caseous necrosis.

Figure 41-130. Category I renal trauma. There is a small cortical laceration (*arrowhead*) involving the left kidney. An associated small perinephric hematoma is present (*arrow*).

Imaging Classification and Management

Categorization of renal injuries according to severity provides a helpful guide to patient management. Renal injuries are classified into four categories on the basis of imaging findings.⁷² Category I lesions (75% to 85% of cases) are clinically insignificant; they consist of contusions and small corticomedullary lacerations that do not communicate with the collecting system (Fig. 41-130). They are managed nonoperatively.^{66, 72} Category II lesions (10% of cases) are more serious and comprise major lacerations through the renal cortex extending to the medulla or collecting systems with or without urinary extravasation (Fig. 41-131). Many of these lesions are managed nonoperatively. However, surgery is sometimes required in patients with extensive hemorrhage or urinary extravasation and a large amount of nonviable renal tissue.¹²² Category III lesions (5% of cases), which are catastrophic, consist of shattered kidney (multiple deep lacerations) (Fig. 41-132) and injury to the renal pedicle (Figs. 41-132 to 41-134). The rare entities of ureteropelvic junction avulsion and laceration of the renal pelvis are designated as category IV lesions. Category III and IV renal lesions usually require surgical intervention. Subcapsular and perinephric hematomas may occur in any of the categories of renal trauma,

Figure 41-131. Category II renal trauma. A renal laceration (*not shown*) involved the collecting system, resulting in contrast extravasation into the right perinephric space (*arrow*). The lesion responded to conservative management.

Figure 41-132. Category III renal trauma—shattered kidney. There are multiple right renal lacerations with the fragments separated by blood clot. An associated perinephric hematoma (arrow) is present. A right nephrectomy was performed.

but when they occur in isolation, they are assigned to category I. Although an image-based classification of renal trauma is useful in guiding management, treatment is often ultimately determined by the patient's clinical status.

Imaging of Renal Trauma

Gross hematuria is the most reliable indication of potentially serious renal damage.¹²² However, the absence of hematuria does not preclude significant renal injury; absence of hematuria has been reported in up to 24% of patients with renal artery thrombosis and in one-third of cases of uretero-pelvic junction injury.^{22, 258} Contrast-enhanced CT is the preferred modality for evaluation of patients with blunt or penetrating abdominal trauma with scans obtained at 70 seconds and 3 minutes after the start of injection of contrast material.¹²²

The three basic types of renal injury demonstrable by

Figure 41-133. Category III renal trauma—occlusion of the right main renal artery. The right kidney shows absence of contrast enhancement except for a subcapsular rim of renal tissue perfused via capsular collateral vessels. Aortography showed occlusion of the main right renal artery. A hematoma (arrow) is present around the renal vascular pedicle.

Figure 41-134. Deep renal laceration (arrowheads) extending into the renal medulla without involvement of the collecting system. A small perinephric hematoma (arrow) is present.

CT are contusions, lacerations, and infarcts, any of which may be further complicated by intrarenal or extrarenal hematomas or by urinary extravasation. The mildest form of renal injury is the contusion, characterized by an amorphous, interstitial extravasation of blood and edema. On unenhanced CT scans, the affected kidney zones may show focal swelling and irregular infiltrates of high-density fresh blood. On contrast-enhanced CT, renal contusions appear as ill-defined, round or ovoid areas of hypoattenuation. They may also appear as small interstitial accumulations of contrast material staining on delayed images (striated nephrogram).^{72, 122, 204}

Superficial lacerations are limited to the renal cortex; deep lacerations extend into the medulla (see Fig. 41-134), where they may enter the collecting system or transect the kidney.²⁰⁴ Contrast extravasation is often seen in the perinephric space (see Fig. 41-131). In patients with multiple lacerations (shattered kidney), the fragments are separated and surrounded by blood clot (see Fig. 41-132).²⁰⁴ Thrombosis or laceration of a segmental branch of the renal artery produces a focal area of renal infarction. Infarcts typically appear as peripherally based, wedge-shaped areas of parenchyma that fail to enhance during both the corticomedullary and pyelographic phases of CT (Fig. 41-135).⁹⁸ Post-traumatic bleeding is commonly associated with all injuries to the kidney. Hematomas may be intrare-

Figure 41-135. Focal renal infarction after blunt trauma. The nephrogram is absent anteriorly (arrow) in the right kidney. "Rim" cortical perfusion of the infarct is present.

Figure 41-136. Left perinephric urinoma (arrows) secondary to blunt trauma to a hydronephrotic left kidney. Hydronephrosis was due to congenital ureteropelvic junction obstruction.

nal or subcapsular or may involve the perinephric or pararenal spaces. The most significant vascular injury after blunt trauma is thrombosis of the main renal artery.¹²³ Main renal artery injuries can be diagnosed on CT through the use of the criterion of absence of renal contrast enhancement with or without cortical rim sign (see Fig. 41-133).¹⁸⁷ Other findings that suggest the diagnosis of pedicle injury include a hematoma surrounding the renal hilus (see Fig. 41-133) and abrupt cutoff of the contrast-filled renal artery.⁷² Acute renal vein occlusion may be suspected if the kidney is enlarged and shows thrombus in the renal vein. Venography may be performed if injuries to the renal vein and inferior vena cava are suspected, because CT may not reliably detect venous laceration.¹²²

Ureteropelvic junction injuries are rare. In these patients CT typically demonstrates excellent excretion of contrast material with an intact intrarenal collecting system, but with medial perinephric urinary extravasation rather than lateral urinary extravasation in category II injuries with involvement of the collecting system. A circumrenal urinoma may be seen around the affected kidney, but typically, there is no perinephric hematoma.¹²²

Abnormal kidneys, including hydronephrotic kidneys (Fig. 41-136), ectopic kidneys, and horseshoe kidneys (Fig. 41-137) as well as kidneys containing neoplasms or cysts, may sustain injury secondary to minor trauma.²¹⁸ Gadolinium-enhanced MRI may be used to assess suspected renal injury when the use of iodinated contrast material is contraindicated.¹³⁹

Renal Blood Flow Disorders

Renal Hemorrhage

CT is the most valuable examination in the evaluation of patients with suspected acute renal hemorrhage because it accurately diagnoses the presence and location of such hemorrhage and often shows the underlying cause.^{14, 238} Renal hemorrhage may be suburothelial, intraparenchymal, subcapsular, perinephric, or pararenal in location or may involve the renal sinus.^{56, 80, 135, 192}

Causes. The most common cause of renal hemorrhage is trauma, either blunt or penetrating (Figs. 41-137 and 41-138). Extracorporeal shock wave lithotripsy for nephro-

Figure 41-137. Injury of horseshoe kidneys. A, Bilateral perinephric hematomas (arrows) are present. B, A caudal CT scan shows a hematoma (white arrow) involving the isthmus connecting the two kidneys. There is contrast extravasation (black arrow) from the left collecting system because of a laceration.

lithiasis is another form of renal trauma not infrequently associated with parenchymal and perinephric hemorrhage (Fig. 41-139).¹⁹² Spontaneous (nontraumatic) renal hemorrhage may be caused by anticoagulation, blood dyscrasias

Figure 41-138. Fat-suppressed T1-weighted MR image (TR = 600 msec, TE = 17 msec) shows a high-intensity left perinephric hematoma (arrow) due to a renal biopsy performed 2 weeks earlier. Loss of corticomedullary differentiation is due to chronic renal disease.

Figure 41-139. Left perinephric hematoma secondary to extracorporeal shock wave lithotripsy. *A*, An unenhanced CT scan reveals anterior displacement of left kidney (*black arrowheads*) by high-density hematoma (*arrow*). There is a calculus (*open arrow*) in the collecting system. The hematoma is limited posteriorly by the posterior renorenal bridging septum, which separates it from the thickened posterior renal fascia (*white arrowheads*). *B*, The hematoma (*white arrow*) extends into the infrarenal fascial cone (*arrowheads*). Infrarenal extension confirms the perinephric location of the hematoma and distinguishes it from a subcapsular hematoma. The left ureter (*curved arrow*) contains a stent and is displaced anteriorly.

(Fig. 41-140), renal infarction, polyarteritis nodosa (Fig. 41-141), renal aneurysms and arteriovenous malformations, RCC, AML, (see Fig. 41-104), renal abscess, renal vein thrombosis, and rupture of hemorrhagic solitary cysts (Fig. 41-142) or of hemorrhagic cysts in renal cystic disease (see Figs. 41-32 and 41-45).^{14, 146, 150} Some cases are idiopathic.¹⁴ RCC is probably the most common cause of spontaneous subcapsular and perinephric hemorrhage.

Findings on CT. Recent renal hemorrhage is characterized by high-attenuation blood (50 to 90 HU), which are best shown by unenhanced CT scans (see Fig. 41-139). Postcontrast scans should also be obtained to facilitate identification of disorders such as small neoplasms causing spontaneous renal hemorrhage. Suburothelial hemorrhage is characterized on CT by thickening of the wall of the renal pelvis and upper ureter by blood that has a high-attenuation value on unenhanced scans.¹³⁵ Spontaneous hemorrhage into the renal sinus is characterized by a high-density blood collection in the renal sinus with displacement of the renal pelvis (Fig. 41-143).⁸⁰ Renal sinus hematomas usually resolve spontaneously, as shown by follow-up CT. Both suburothelial and renal sinus hemorrhage occur most commonly in patients undergoing anticoagulation therapy or with bleeding or coagulation disorders.^{80, 135}

On an unenhanced CT scan, a recent subcapsular hematoma is characterized by a mass with a higher attenuation value than that of adjacent renal parenchyma (see Fig. 41-140). Pressure on the underlying renal parenchyma characteristically causes flattening of the kidney, elevation of the renal capsule, and medial displacement of the collecting system. Sometimes, subcapsular hematomas fail to resolve, causing chronic fluid collections that compress the renal parenchyma. This, in turn, may cause hypertension by reducing renal blood flow, thereby triggering the renin-angiotensin-aldosterone system. This clinical entity is called the *Page kidney*.¹²² The walls of chronic subcapsular hematomas may eventually calcify (Fig. 41-144).

Perinephric hematomas involve the fat between the renal capsule and the renal fascia. The configuration of such hematomas is determined largely by the bridging septa in the perinephric fat.¹³⁶ When a hematoma is confined by the

Figure 41-140. Right subcapsular and perinephric hemorrhage associated with idiopathic thrombocytopenia. *A*, An unenhanced CT scan shows indentation of the lateral border (*arrowheads*) of the right kidney by a denser subcapsular hematoma. A smaller perinephric hematoma (*arrows*) is also present. *B*, A contrast-enhanced CT scan shows that the hematoma is less dense than the enhanced renal parenchyma. (From Levine E, Grantham JJ, MacDougall ML: Spontaneous subcapsular and perinephric hemorrhage in end-stage kidney disease: Clinical and CT findings. *AJR Am J Roentgenol* 148:755-758, 1987.)

Figure 41-141. Multiple renal infarcts and perinephric hemorrhage complicating polyarteritis nodosa. *A*, A left perinephric hematoma (arrow) is contained by the posterior renorenal bridging septum. There are several wedge-shaped infarcts (arrowheads) involving the renal parenchyma. *B*, A left selective renal arteriogram shows multiple small aneurysms arising from interlobar arteries. Active contrast extravasation (arrows) in the lower pole indicates bleeding from a ruptured aneurysm. The patient showed response to selective embolization of the feeding artery. (Courtesy of James Bergh, M.D., Overland Park, Kan.)

Figure 41-142. Right perinephric hematoma (arrow) probably due to rupture of a simple renal cyst. The cyst (arrowheads) is flattened by the hematoma.

Figure 41-143. Acute hemorrhage (arrow) in the left renal sinus associated with anticoagulant therapy displaces the renal pelvis.

posterior renorenal bridging septum, it may compress and indent the renal surface, and because it is separated from the renal fascia, it may simulate a subcapsular hematoma (see Figs. 41-139 and 41-141).¹³⁶ However, although subcapsular hematomas are confined to the kidney by the renal capsule, perinephric hematomas often extend caudally below the kidney into the cone of renal fascia (see Fig. 41-139).

CT often shows the cause of spontaneous subcapsular and perinephric hematomas.²³⁸ RCCs or AMLs associated with such hematomas may be suspected on CT from the presence of a distinct mass clearly different in character from the surrounding hemorrhage.¹⁴ RCCs present as heterogeneous, enhancing solid masses or as cystic masses, manifest whereas an AML is suggested by the presence of tumor fat (see Fig. 41-104).¹⁴ CT may show that hemorrhage originated in either a solitary renal cyst (see Fig. 41-142)⁵⁶ or a cyst associated with hereditary or acquired renal cystic disease (see Figs. 41-32 and 41-45).^{146, 150} If CT shows no cause for hemorrhage, renal angiography may help with diagnosis by demonstrating underlying disorders such as angiitis, renal aneurysms, arteriovenous malformations, and polyarteritis nodosa (see Fig. 41-141).¹⁴

Management. CT is valuable in the follow-up and management of renal hemorrhage whether spontaneous or due to trauma. RCCs complicated by hemorrhage are managed with nephrectomy, whereas underlying hemorrhagic renal cysts, renal infarcts, or AMLs can usually be managed conservatively.^{14, 150} When the bleeding is extensive and the patient is unstable, renal angiography with embolization (see Fig. 41-141) or, occasionally, surgery may be necessary to stop the bleeding.^{27, 150} Patients with spontaneous renal hemorrhage who have no demonstrable cause for the bleeding or for whom the diagnosis of the cause of the hemorrhage is in doubt should also receive conservative management. To exclude an underlying RCC, however,

Figure 41-144. Chronic calcified subcapsular hematoma in a hypertensive man. The low-density (17 HU) posterolateral mass with peripheral calcification (*arrows*) causes anteromedial displacement of the right kidney as seen on unenhanced (A) and contrast-enhanced (B) CT scans.

serial CT should be used to monitor such patients until the hematoma completely resolves.¹⁴ This approach avoids unnecessary nephrectomy in patients who have spontaneous renal hemorrhage with benign renal disease or no underlying disease.^{14, 27}

Renal Infarction

Renal infarction may be due to renal artery thrombosis or embolism, vasculitis as in polyarteritis nodosa, trauma, sickle cell disease, or aortic dissection. The most common cause is thromboembolism from cardiovascular disease.¹²³ CT findings depend on both the extent and age of the infarction. The size and shape of a renal infarct is determined by the size of the occluded artery. If the main renal artery is occluded, global infarction of the kidney occurs (see Fig. 41-133). On contrast-enhanced CT scans, the affected kidney shows lack of enhancement, apart from a high-density cortical rim reflecting perfusion of the preserved outer rim of the cortex by collateral vessels (see Fig. 41-133).¹¹⁶ The renal collateral circulation is supplied via renal capsular vessels, peripelvic vessels, and periureteral vessels.

If a major renal artery branch is occluded, an acute focal infarct results, which manifests as a wedge-shaped low-attenuation renal parenchymal lesion on a contrast-enhanced CT scan. The base of the wedge is contiguous with the renal capsule and the apex is directed toward the renal hilus.⁹⁸ There is usually sharp margination between infarcted tissue and the adjacent normal nephrogram (Fig. 41-145). A rim sign is often seen on the capsular margin of the infarct. Emboli and vasculitis cause multiple, often bilateral, focal renal infarcts (Fig. 41-146).²⁹² Unilateral infarcts are often the result of renal trauma, which is also a common cause of global renal infarction (see Fig. 41-133).²⁹² When smaller intrarenal arteries are occluded, the CT findings are less specific and consist of multiple low-attenuation defects that are scattered throughout the nephrogram although usually peripherally located. Vascular

thrombosis in sickle cell disease causes multiple foci of “slitlike” areas of low attenuation.²⁹²

Both acute focal and global infarcts may be associated with subcapsular or perinephric blood or fluid collections and thickening of the renal fascia (see Fig. 41-146).²⁹² Old infarcts manifest on CT as renal cortical scars or as a small, shrunken kidney (Fig. 41-147).¹²³

The main CT differential diagnosis of acute renal infarction is acute pyelonephritis, because both conditions (1) often demonstrate wedge-shaped, low-attenuation renal lesions on CT and (2) often manifest as acute onset of flank pain and fever. A cortical rim sign should strongly suggest the diagnosis of renal infarction (see Fig. 35-146), because it is usually not seen in acute pyelonephritis.²⁹² Small renal infarcts may also be confused with focal lymphomatous lesions or metastases on CT.

Figure 41-145. Focal renal infarct associated with emboli from a prosthetic mitral valve. The lesion (*arrow*) manifests as a wedge-shaped zone of low attenuation. The base of the wedge is contiguous with the renal capsule, and the apex is directed toward the renal hilus. There is a straight, sharp margin between the infarct and normal renal tissue. A rim of perfused tissue is seen on the capsular margin of the infarct.

Figure 41-146. Left renal infarcts (arrowheads) associated with fibrodysplastic occlusions of branches of the renal artery. Both lesions show subcapsular rims of perfused tissue, and there is associated thickening of the anterior and posterior renal fascia (arrows).

Renal Artery Stenosis

Secondary hypertension due to diseases of the renal arteries (i.e., renovascular hypertension) accounts for about 1% to 5% of all cases of hypertension.¹⁷⁶ Atherosclerosis and fibrodysplastic disease are the most common causes of significant renal artery narrowing. Although there are several tests for evaluating patients with suspected renovascular hypertension, the standard for the diagnosis of renal artery stenosis is angiography, with response to treatment the proof of its significance.²¹⁵ CT angiography (CTA) and MRA provide noninvasive means to obtain anatomic information. CTA and gadolinium-enhanced three-dimensional MRA seem to be preferred in patients referred for evaluation of renovascular hypertension.²⁸⁰

Computed Tomography. The renal arteries are not always well shown by conventional CT. However, significant renal artery disease may be suspected from conventional dynamic CT scans if the affected kidney shows prolonged corticomedullary differentiation in comparison with the normal side (Fig. 41-148). Global loss of renal parenchyma, if present, may be ancillary evidence of chronic arterial stenosis or occlusion (see Fig. 41-148).¹⁶

Figure 41-147. Bilateral renal scarring due to old infarcts in a hypertensive patient.

Figure 41-148. Right renal artery stenosis. A, Dynamic CT scan after a rapid intravenous injection of contrast agent shows prolonged corticomedullary differentiation in the right kidney as compared with the left kidney, for which the nephrogram is almost homogeneously dense. The right kidney also shows global atrophy. B, A contiguous caudal image reveals a calcified atherosclerotic plaque (arrow) at the origin of the right renal artery. (From Birnbaum BA, Bosniak MA, Megibow AJ: Asymmetry of the renal nephrogram on CT: Significance of the unilateral prolonged cortical nephrogram. *Urol Radiol* 12:173-177, 1991.)

The development of helical (spiral) CT and now multi-detector (multislice) CT with subsecond speed allows volumetric acquisitions to be obtained during a single breath-hold. Multislice CT systems allow the simultaneous acquisition of multiple slices per gantry rotation. In combination with faster gantry rotation times of 0.5 second, the abdominal structures can be displayed in higher spatial and temporal resolution. The advantage of this technique is that it eliminates the respiratory misregistration that often degrades the image quality.¹³⁴ Sensitivity and specificity for significant renal artery stenosis with single-slice helical CT are 88% to 97% and 83% to 89%, respectively, compared with catheter angiography.

Multislice CTA exceeds MRA in spatial resolution and is now able to display even small vascular side branches.²¹² Compared with catheter angiography, CTA has a sensitivity of 95% to 100% and a specificity of 99% to 100% for detection of accessory renal arteries (Fig. 41-149).⁷⁷ The renal vascularity is evaluated during the vascular phase, which occurs approximately 15 to 25 seconds after the

Figure 41-149. 3D multiplanar reconstruction, posterior view. There is slight narrowing of the right renal artery in its midcourse, and both renal arteries are of normal caliber at their origin (arrows). IVC = inferior vena cava.

Figure 41-150. 3D multiplanar reconstruction, posterior view, with overlying 12th rib. Arrows point to the renal arteries.

start of injection of intravenous contrast material administration.¹²³ Typical acquisition parameters for CTA of the renal artery include a collimation of 3 mm, a pitch of 1.5 to 2.0, a reconstruction interval of 1 to 2 mm, a scan delay of 25 seconds after the start of contrast material, and an injection rate of 3 mL/sec or greater.^{208, 228, 229} Images should be reconstructed with 50% overlap to improve detection of renal artery stenosis and 3D reconstruction.

Commonly used 3D visualization techniques include surface rendering, maximum intensity projection (MIP), and volume rendering. Volume rendering is superior to MIP and surface rendering because it uses the volume data and can provide lifelike images, including color. This permits multiplanar reconstruction (MPR) in any plane (Fig. 41-150). This technique is very useful in the pretransplantation evaluation of renal donors and in presurgical planning.

MR Angiography. MRA with gadolinium enhancement has a sensitivity of 100% and a specificity in the range of 93% to 97% for detection of proximal renal artery stenosis (Fig. 41-151).^{58, 211, 259} In the past, both time-of-flight imaging and phase-contrast imaging were used; both methods have been virtually replaced by breath-hold 3D gadolinium MRA (3D-Gd). 3D-Gd breath-hold sequences prevent image degradation from respiratory motion, reduce the acquisition time, and overcome the problem of satura-

tion of in-plane blood flow.²³⁵ The dose of gadolinium is usually 0.2 mmol/kg. The typical injection rates are 2 to 3 mL/sec. Commonly, four different degrees of stenosis are assessed, based on the reduction of vessel diameter: normal (0%); mild (<50%); moderate (50% to 75%); or severe (75%) (Fig. 41-152).²³⁵ In about 20% to 30% of patients, the kidney is supplied by more than one renal artery (Fig. 41-153).²³⁵ 3D-Gd-enhanced MRA allows an accurate diagnosis of proximal renal artery stenosis without the risks associated with nephrotoxic contrast agents, ionizing radiation, or arterial catheterization.

Following is a general outline of the renal artery stenosis protocol. A torso coil centered at midabdomen is used, with peripheral gating and respiratory bellows. An 18-gauge intravenous line is placed in the antecubital vein. The following sequences are obtained:

1. Breath-hold coronal-large field of view of the upper abdomen.
2. Non-breath-hold, sagittal T1-weighted spin-echo image over the aorta (6–8 slices) about 4–6 mm thick, giving a good target for Smartprep tracker placement.
3. Breath-hold coronal SSFSE of the kidneys (for cysts) prescribe off series 2.
4. Precontrast coronal 3D enhanced fast GRE (EFGRE) sequence through the territory of interest (trial run); 3 mm thick (no gap because it is 3D). Cover from the celiac axis to groin. Keep scan time under 25 to 30

Figure 41-151. A and B, Gadolinium-enhanced MR angiogram shows stenosis of proximal right renal artery.

seconds for renal arteries. Maximize spatial resolution, increasing phase-encoding steps (can be 224 or 256 for some patients), using partial number of excitations (NEX).

5. Repeat step 4: Coronal plane 3D EFGRE with tracker

placed just above the origin of renal arteries + gadolinium, with the patient's arms positioned up above the head to avoid the wrap-around artifact. Run this sequence two times successively, allowing the patient to take three deep breaths before each run.

Figure 41-152. Gadolinium-enhanced MR angiogram shows severe stenosis of right renal artery at its origin (arrow). K = kidney.

Figure 41-153. Gadolinium-enhanced MR angiogram (EFGRE 3D) composite image shows two left renal arteries (arrows) and a single right renal artery (arrowhead).

Figure 41-154. Bilateral acute renal cortical necrosis complicating aortic dissection (arrow). There is no enhancement of the renal cortex apart from a thin subcapsular rim perfused by capsular collateral vessels. Enhancement of the renal medulla is preserved. (Badiola-Varela CM: Acute renal cortical necrosis: Contrast-enhanced CT and pathologic correlation. *Urol Radiol* 14: 159-160, 1992.)

- Optional: Flow-gradient axial from origin of the celiac axis to the iliac arteries in an elderly patient if an aneurysm is suspected; this helps visualization of the outer wall of the aneurysm.

Acute Cortical Necrosis

Acute cortical necrosis, a rare form of acute renal failure, results from ischemic necrosis of the renal cortex with sparing of the medulla.¹²³ The most common cause is hemorrhage in the third trimester of pregnancy, most often associated with placental abruption. Other causes are septic abortion, severe trauma with shock, transfusion reaction, severe dehydration, certain toxins including snake venom,

the hemolytic-uremic syndrome, and acute aortic dissection.¹¹² Some of these conditions appear to act by producing renal cortical vasoconstriction, causing necrosis of the renal cortex.⁵² The condition is usually bilateral, but may occasionally be unilateral.¹¹²

Contrast-enhanced CT shows a distinctive nephrographic pattern characterized by a zone of unenhanced cortex between a rim of enhancing subcapsular cortex and the enhancing juxtamedullary cortex and medulla (Fig. 41-154).^{112, 172} Global atrophy of the kidneys occurs within a few months, leading to small, smooth kidneys. A dense linear “tram-line” calcification can form in the renal cortex.⁶⁷

Renal Artery Aneurysm and Arteriovenous Communications

Renal artery aneurysms may be saccular, fusiform, or intrarenal. The most common cause of aneurysms of the renal artery is atherosclerosis.¹⁶² Other causes include medial fibrodysplasia, pregnancy, neurofibromatosis, and Ehlers-Danlos syndrome. Intrarenal aneurysms are usually associated with polyarteritis nodosa and Wegener’s granulomatosis.¹²³ Most aneurysms are extrarenal (Fig. 41-155). Aneurysms of the main renal artery or its major branches may show rimlike calcification (Fig. 41-156) and significant enhancement on CT scans. Renal infarcts secondary to emboli from mural thrombus in the aneurysm may be seen on contrast-enhanced CT.¹²³ Demonstration of small intrarenal aneurysms requires selective renal arteriography.

Renal arteriovenous communications that are developmental are called arteriovenous malformations. Arteriovenous fistulas (AVFs) account for 70% to 80% of arteriovenous communications in the kidney.⁴³ Penetrating trauma is the most common cause of AVF; other causes include

Figure 41-155. Left renal aneurysm A, Contrast-enhanced axial CT shows an extrarenal large aneurysm with thrombus (arrow) and focal calcification in its wall posteriorly. The embolus from the aneurysm has resulted in segmental infarct (large arrowhead). B, The selective angiogram of the left kidney confirms the extrarenal aneurysm of the renal artery.

Figure 41-156. Bilateral atherosclerotic renal artery aneurysms (arrows) with peripheral calcification.

surgery, tumors, and inflammation; AVFs may also be idiopathic.¹²³ Small intrarenal AVFs or arteriovenous malformations are best diagnosed with selective renal arteriography. However, larger lesions may be calcified and may occur in the renal sinus where they may be confused with other

renal masses (Fig. 41-157). These vascular lesions are best assessed on contrast-enhanced CT. A nonthrombosed lesion enhances to the same extent as the adjacent aorta. A thrombosed lesion shows no contrast enhancement (see Fig. 41-157). Visualization of an enlarged feeding renal artery and draining vein confirms the nature of an AVF (see Fig. 41-157).

Renal Vein Occlusion

Renal vein occlusions may be categorized into the following five groups:

1. Extrinsic occlusion of the renal vein by an adjacent neoplasm, e.g., pancreatic carcinoma or lymphoma.¹⁵⁵
2. Direct renal vein extension of RCC or adrenal neoplasms.¹¹¹
3. Renal vein thrombosis associated with primary renal disease. About 20% of patients with the nephrotic syndrome due to such causes as membranous glomerulonephritis, lupus erythematosus, and amyloidosis have renal

Figure 41-157. Bilateral renal artery pseudoaneurysms in a patient with a history of previous trauma. *A*, Contrast-enhanced CT scan shows an enhancing mass with peripheral calcification (arrow) in the lower part of the right renal hilus. There is also a nonenhancing mass with peripheral calcification (curved arrow) in the lower part of the left renal hilus. *B*, Cephalad scan reveals significant enlargement of the right renal artery (a) and vein (v), indicating an arteriovenous fistula. The left renal vein (arrow) is normal in size. *C*, Right selective renal arteriogram reveals enlargement of the right renal artery (arrow) and vein (curved arrow). The calcified pseudoaneurysm is opacified (open arrow). *D*, The left renal artery pseudoaneurysm (arrows) does not opacify because of thrombosis.

vein thrombosis, which may be acute or chronic.²⁹⁴ In adults, the most common underlying abnormality is membranous glomerulonephritis.¹²³

4. Secondary renal vein occlusion or thrombosis may occur when the inferior vena cava is thrombosed after caval extension of thrombus from pelvic or leg veins.
5. Renal vein thrombosis, which may occur as a primary phenomenon in infants with a history of maternal diabetes, sickle cell disease, hemoconcentration states such as diarrhea and sepsis, and hypoxia in cyanotic congenital heart disease.⁹⁴ Adults with hypercoagulable states may also experience renal vein thrombosis.

The clinical and imaging findings in renal vein thrombosis depend on the severity of occlusion, the rapidity of onset, the location of the thrombus, and the cause. Left renal vein thrombosis is more common. A classic acute presentation consists of flank pain, hematuria, and loss of renal function.¹²³ Patients with chronic renal vein occlusion are usually asymptomatic.

Contrast-enhanced CT is an excellent method for the noninvasive diagnosis of renal vein thrombosis, provided that renal function is normal. CT permits differentiation between acute renal vein thrombosis and conditions that have similar clinical presentations, such as acute pyelonephritis, acute renal infarction, and acute renal obstruction.⁸⁸

Renal vein thrombosis is generally unilateral. In acute and subacute cases, an enlarged, swollen kidney is seen on CT. The nephrogram in the affected kidney is initially diminished because of impaired renal perfusion; however, once the nephrogram develops, it persists for a prolonged period and there is often prolonged enhancement of the renal cortex relative to the renal medulla (Fig. 41-158).¹²³ Calyceal opacification is often delayed, diminished, or absent in the affected kidney. Stranding of the perinephric fat due to edema and thickening of the renal fascia may occur. Enlarged perirenal collateral veins are often noted. Perinephric hemorrhage may occur. On CT, the renal vein is

Figure 41-158. Renal vein thrombosis. Dynamic CT scan shows a low attenuation clot (*arrow*) in a partially thrombosed left renal vein. There is prolonged corticomedullary differentiation in the left kidney compared with the right kidney, which exhibits a homogeneous nephrogram. (From Birnbaum BA, Bosniak MA, Megibow AJ: Asymmetry of the renal nephrogram on CT: Significance of the unilateral prolonged cortical nephrogram. *Urol Radiol* 12:173-177, 1991.)

Figure 41-159. Renal vein thrombosis associated with the nephrotic syndrome. A, Low-density thrombus is present in a retroaortic left renal vein (*arrowheads*) and in the adjacent inferior vena cava (*arrow*). B, Spin-echo MR image (TR = 650 msec, TE = 30 msec) shows high signal thrombus in the retroaortic left renal vein (*arrow*) and in the adjacent inferior vena cava (*black arrowhead*). The aorta (*white arrowhead*) shows normal blood flow.

commonly enlarged and may show a filling defect because of thrombus (see Fig. 41-158).^{87, 247} Thrombosis of the inferior vena cava at or near the renal vein orifices occurs in about 40% to 50% of patients with renal vein thrombosis (Fig. 41-159).

Demonstration of venous thrombus is facilitated by scanning during the peak phase of vascular opacification after bolus injection of contrast medium and by obtaining 5-mm-thick sections (see Fig. 41-158). Infarction of the affected kidney may occur, and long-term follow-up by CT may reveal severe atrophy and poor function in the affected kidney.⁸⁷

Chronic renal vein thrombosis is often a silent complication of the nephrotic syndrome.⁸⁴ CT frequently shows the presence of venous thrombus (see Fig. 41-159). In the chronic phase of renal vein thrombosis, the affected renal vein becomes attenuated because of retraction of the clot and extensive collateral vessels develop along the proximal to middle ureter and around the kidney.¹²³

MRI is widely used for detecting renal vein extension of RCC; it can also be used in the evaluation of nonneoplastic renal vein thrombosis. MRI is most useful for evaluating patients with significant renal functional impairment and symptoms suggesting renal vein thrombosis. Renal vein thrombus may be shown on T1-weighted spin-echo pulse sequences when the signal void of flowing blood in the renal vein is replaced by high signal because of thrombus (see Fig. 41-159). Gradient-echo technique shows thrombus as a filling defect of medium signal intensity that

replaces the high signal of flowing blood (see Fig. 41–69). Coronal MRI helps determine the extent of vena caval involvement. MRI in patients with acute renal vein thrombosis may also show loss of corticomedullary differentiation on T1-weighted spin-echo images, increased signal in the affected kidney on T2-weighted images, renal fascial thickening, and renal enlargement.¹³¹

Helical CT of Urinary Tract Stones

Plain film radiography, excretory urography, retrograde pyelography, and ultrasonography are utilized in various combinations for the diagnosis of urinary tract stones in patients presenting with flank pain. CT has virtually replaced all other imaging modalities for this purpose. Unenhanced helical CT for the evaluation of patients with flank pain was first described by Smith and associates in 1994 in 1995.²⁵² Helical unenhanced CT is superior to other imaging modalities in diagnosis of urinary tract calculi. Also, it can diagnose other causes of flank pain such as appendicitis, diverticulitis, pancreatitis, bowel obstruction, and intussusception.^{161, 251}

Technique

The CT examination for suspected ureterolithiasis is performed from the top of the kidneys to the base of the bladder, without the use of intravenous or oral contrast material. A collimation of 5 mm with a pitch of 1 is recommended for single-detector spiral CT; 2.5-mm collimation with reconstruction at 2.5 mm and a pitch of 0.8 to 1 for multidetector CT is preferred. The presence of distended urinary bladder at the time of imaging better defines the ureteral insertions.²⁵¹ Utilizing a pitch of 2 results in decreased radiation exposure without much sacrifice in the quality of scan.⁵⁹ The helical CT data are acquired in breath-holding, thus avoiding the respiratory misregistration artifact and allowing the retrospective reconstruction to delineate small calculi. The introduction of multidetector CT has further reduced the scan performance time, enabling the study to be completed in about 10 to 15 seconds.

CT Findings

Virtually all stones (including uric acid stones) are of sufficient radiographic attenuation to be readily visible on CT,²⁵¹ except for stones associated with protease inhibitors used for treating human immunodeficiency virus (indinavir).^{20, 263} In the presence of flank pain, the primary CT finding in ureteral obstruction is the identification of a stone within the lumen of the ureter (Fig. 41–160).²⁵¹ Even calculi of submillimeter size can be easily identified. The most common sites of impaction are the ureteropelvic junction (35%) (Fig. 41–161), midureter (7%), distal ureter (33%), and ureterovesicular junction (18%). (Fig. 41–162). In one study 8% of the stones were already present in the bladder at the completion of the CT examination.⁵⁰ The search for the ureteric calculi should extend from the renal pelvis to the bladder. There is no substitute for establishing

Figure 41–160. Non-contrast renal CT protocol. Axial image demonstrates a left ureteric calculus with surrounding ureteric wall edema called the soft tissue rim sign (arrow). Part of the left kidney (K) is seen. There is some right perinephric edema (arrowhead) because the patient had bilateral ureteric calculi (not shown).

continuity of a calcification within the ureteral lumen on sequential images.⁴⁹ The *soft tissue rim sign* (see Fig. 41–160) can be used to identify the ureter; it represents edema of the ureteral wall at the level where a stone has become impacted.^{105, 252} Approximately 77% of ureteral stones have the soft tissue rim sign.⁴⁹ Presence of this sign is specific for the diagnosis of ureterolithiasis, however, absence of the sign does not preclude such a diagnosis.¹²¹

Differentiating between a phlebolith and a ureteric calculus is a significant problem especially in patients with minimal retroperitoneal fat. Phleboliths, which are common

Figure 41–161. Non-contrast renal CT protocol. Axial image demonstrates a 3- to 4-mm calculus (arrow) in the right ureteropelvic junction with mild hydronephrosis (arrowhead).

Figure 41-162. Non-contrast renal CT protocol. Axial image demonstrates a 2- to 3-mm calculus in the ureterovesicular junction (arrow) in a patient with left flank pain and hematuria.

in the pelvis, arise from thrombi in the pelvic veins and are not often seen in the mid- and upper abdomen except when present in gonadal veins. The presence of the *comet tail sign*—an adjacent eccentric, tapering soft tissue mass corresponding to the noncalcified portion of a pelvic vein—helps differentiate between ureteric calculus and phlebolith.^{13, 23} CT is poor in identifying the central lucency present in a phlebolith on plain radiographs²⁷⁴ and is not helpful in the differentiation of phlebolith and calculus.

When present, two important secondary CT signs of obstruction, ureteral dilatation and perinephric stranding (Fig. 41-163), are helpful in the diagnosis of ureteral obstruction.²⁵¹ Presence of ureteral dilatation has a positive predictive value of 90% and a negative predictive value of 89% for diagnosis of ureteral obstruction.⁵⁰ The dilated, urine-filled ureter, a reliable guide to the point of obstruction, is followed with sequential CT images until a change of caliber is seen (see Fig. 41-113). The mean diameter of the normal ureter on CT is 1 to 2 mm. The symptomatic side is compared with the normal side; it is important not to mistake a ureter for the gonadal vein.

Stranding of the perinephric fat on the symptomatic side

Figure 41-164. Non-contrast renal CT protocol. Axial image shows dilated calyx in the right renal upper pole (arrow) secondary to obstruction of the ureteropelvic junction (not shown).

represents fluid within the bridging septa due to increased lymphatic pressure.⁴⁹ This finding has a positive predictive value of 92% and a negative predictive value of 84% for diagnosis of ureteral obstruction.²⁵³ Perinephric stranding is most commonly seen in patients with acute or chronic ureteral obstruction; however, in the absence of obstruction, stranding can be seen in pyelonephritis, renal vein thrombosis, renal infarction, trauma, and renal tumor with hemorrhage.²⁵¹ Periureteral stranding is less common and is rarely seen in the absence of perinephric stranding.

Collecting system dilatation is best identified in the upper pole and lower poles. Dilated calyces and infundibula appear as rounded, fluid-filled structures that partially obliterate the renal sinus fat when compared with the contralateral side (Fig. 41-164).⁴⁹ Its presence yields a positive predictive value of 93%.²⁵³ After ureteral obstruction, renal enlargement may be seen; its presence has a

Figure 41-163. Non-contrast renal CT protocol. A, Axial image shows left ureteric dilatation (arrow); compare it with contralateral ureter (arrowhead) in a patient with horseshoe kidney. He had a small left ureterovesicular calculus (not shown). B, Right perinephric stranding (arrow) secondary to distal ureteric calculus (not shown).

Figure 41-165. A and B, Non-contrast renal CT with “white pyramid sign.” Axial image shows hyperattenuating pyramids in the left kidney (arrows). C, The right kidney is edematous, with minimal perinephric stranding (arrowhead), mild hydronephrosis with absence of hyperattenuating pyramids secondary to a small calculus in the right ureterovesicular junction calculus (arrow).

positive predictive value of 86% for diagnosis of ureteral obstruction.²⁵³

Unilateral absence of the “white pyramid” has been described as an additional secondary sign of urinary tract obstruction (Fig. 41-165).²²⁷ Bilateral high-attenuation renal pyramids are an occasional incidental finding. Ureteral obstruction may result in tubular hydronephrosis, decreasing the attenuation of the medullary pyramid on the obstructed side. The finding of high-attenuation medullary pyramids in only one kidney suggests the presence of obstruction in the other kidney.⁴⁹

Nephrolithiasis is found in 46% of patients with ureteral stones.²⁵³ Approximately 5% of patients have ureteral dilatation and perinephric stranding without any demonstrable ureteral calculus⁵⁰; this constellation of findings should prompt a differential diagnosis of a passed stone, stone too small to visualize, pyelonephritis, or obstruction unrelated to stone disease. However, the constellation of findings in a patient who is undergoing treatment with a protease inhibitor such as indinavir should suggest the diagnosis of indinavir stone disease (Fig. 41-166).⁴⁹ Indinavir stones are nonopaque on CT scans.²⁰ If the patient shows no evidence of infection, and has never been treated with protease inhibitors, CT scanning should be repeated with intravenous contrast material for further evaluation.

The other common diagnoses detected on unenhanced

CT in patients with flank pain that are unrelated to the urinary tract include ovarian masses (with torsion or hemorrhage), appendicitis, diverticulitis, choledocholithiasis, Crohn’s disease, and pancreatitis. The two most common diagnoses detected on unenhanced CT that are related to the urinary tract but are unrelated to stone disease are pyelonephritis and bladder outlet obstruction.⁵⁰

Retroperitoneal Fibrosis

CT is particularly helpful in evaluating patients with ureteric obstruction secondary to retroperitoneal fibrosis. Retroperitoneal fibrosis may be due to a variety of causes. About 70% of cases are idiopathic (Fig. 41-167). Other causes are various drugs (especially methysergide), previous abdominal surgery or radiation therapy, inflammatory aortic aneurysm (Fig. 41-168), and inflammatory bowel diseases. Retroperitoneal fibrosis may also be caused by a desmoplastic reaction secondary to retroperitoneal spread of some neoplasms, notably lymphomas, and of carcinomas of the breast, stomach, lung, colon, and bladder (Fig. 41-169).⁵

Urinoma

Continued leakage of urine from the collecting system in the presence of urinary obstruction may lead to an

Figure 41-166. Protease inhibitor deposition in a 35-year-old man with human immunodeficiency virus disease who is undergoing indinavir therapy. *A*, Axial non-contrast CT scan reveals hydronephrosis and minimal perinephric stranding of the right kidney. *B*, A more caudal scan shows hydroureter (*arrow*). *C*, More caudal scan demonstrates the persistence of hydroureter to the level of the ureterovesicular junction (*arrow*). No calcification was identified. *D*, Retrograde ureterogram shows multiple filling defects in the distal right ureter. Stricture of the ureter distal to the indinavir fragments is likely caused by recent stone impaction near the ureterovesicular junction. (From Dalrymple NC, Casford B, Raiken DP, et al: Pearls and pitfalls in the diagnosis of ureterolithiasis with unenhanced helical CT. *Radiographics* 20:439-447, 2000.)

Figure 41-167. Idiopathic retroperitoneal fibrosis. *A*, A rim of fibrous tissue (*arrowheads*) surrounds the aorta, which contains calcified atherosclerotic plaques. The fibrous tissue obscures the plane between the aorta and the vena cava (*black arrow*). Fibrous tissue strands (*white arrows*) extend laterally to surround the ureters, which contain stents. There is bilateral calyceal dilatation. *B*, Proton-density weighted MR image (spin-echo, TR = 1800 msec, TE = 15 msec) obtained 6 months after bilateral ureterolysis reveals a periaortic rim of fibrous tissue (*arrows*) with a signal intensity higher than that of muscle. The inferior vena cava (*arrowhead*) is patent but is attached to the fibrous tissue.

Figure 41-168. Retroperitoneal fibrosis and ureteric obstruction due to an inflammatory aortic aneurysm. *A*, There is bilateral hydronephrosis. *B*, Caudal scan shows a calcified atherosclerotic aortic aneurysm (*arrowheads*) surrounded by thick fibrous tissue (*arrows*) that entraps the ureters (*curved arrows*).

Figure 41-169. Malignant retroperitoneal fibrosis due to metastatic gastric carcinoma. There is bilateral hydronephrosis with no contrast excretion on the right. The contrast-enhanced aorta (*a*) is surrounded by an ill-defined mantle of tissue (*arrows*) that displaces the vena cava (*arrowhead*) to the right. There is bilateral renal fascial thickening.

Figure 41-170. Right perinephric urinoma secondary to ureteric obstruction caused by lymph node metastases from a testicular carcinoma. *A*, Perinephric fluid collection causes anterior displacement of the right kidney. Contrast material (*arrow*) is present posteriorly in the perinephric space. The right renal pelvis (*curved arrow*) is dilated. Enlarged retroperitoneal lymph nodes (*L*) are evident. *B*, Caudal scan exhibits contrast material (*black arrow*) tracking posteriorly from a dilated and obstructed right ureter (*white arrow*). There is a bridging septum (*open arrow*) between the renal capsule and the posterior renal fascia.

encapsulated retroperitoneal urine collection called a *urinoma*. Urinomas may be associated with ureteropelvic junction obstruction, retroperitoneal fibrosis, retroperitoneal malignancy, cancer of the renal pelvis, ureter, or bladder, and a variety of conditions that cause bladder outlet obstruction.²⁶⁶ Urinomas may also occur in patients who have experienced penetrating abdominal trauma, renal surgery, or urinary tract instrumentation.²⁶⁶

On CT, a urinoma is usually demonstrated to be confined to the perinephric space by the cone of the renal fascia and often to extend into the infrarenal part of the space. Most urinomas occur posterior to the kidney, which is displaced upward anteriorly and sometimes laterally (Figs. 41–170 and 41–171).²⁶⁶ They often have a thickened wall, which may contain dystrophic calcification (see Fig. 41–171). Urinomas usually contain fluid of uniform water density. Hydronephrosis is usually present and is aggravated by ureteric compression due to the urinoma. The nature of a urinoma may be confirmed by contrast-enhanced CT, which sometimes shows layering of contrast medium in the dependent part of the collection (see Fig. 41–170). Management of urinomas due to urinary obstruc-

tion consists of overcoming the obstruction and excision or drainage of the urinoma.²⁶⁶

Renal Transplants

Radiologic evaluation for suspected surgical complications and of kidney dysfunction in patients with renal transplants is best achieved by renal scintigraphy and ultrasonography. Peritransplant fluid collections, including hematomas, lymphoceles, abscesses, and urinomas, are readily assessed on ultrasonography. Unenhanced CT and MRI are reserved for cases in which ultrasonography fails either because of lack of access due to a recent surgical incision or because the transplant area is obscured by intestinal gas. Contrast-enhanced CT should be avoided because of the potential for nephrotoxicity.

MRI is a suitable alternative in the evaluation of the transplanted kidney and peritransplant region^{3,184}; however, sonography and sonographic-guided biopsy remain the primary imaging and interventional modalities.

Peritoneum and Mesentery

John R. Haaga

As experience with imaging within the abdomen has accumulated, it has become apparent that computed tomography (CT) and magnetic resonance imaging (MRI) are useful for the diagnosis of the many peritoneal and mesenteric problems. Even if a primary peritoneal problem does not exist, many secondary signs that can add valuable insights about other disorders may be observed.

This chapter discusses the normal anatomy and physiology of the peritoneum and mesentery as well as the wide spectrum of pathologic disorders that affect the area. I have also included information on the retroperitoneum as it interrelates to the peritoneum. Inclusion of this material permits a more comprehensive understanding of abdominal problems.

Embryology

The gastrointestinal (GI) tract is formed when the entoderm develops in a tube within the coelomic cavity. It acquires a single-layer covering of mesodermal cells, which evolve from the space between the ectoderm and the endoderm (Fig. 42-1A). The dorsal or posterior mesoderm forms the dorsal mesentery, which eventually composes the visceral peritoneum of the abdomen (the pericardium and pleura in the chest) (Fig. 42-1A).

The anterior splanchnic mesoderms fuse to form the ventral (anterior) mesentery and later completely disappear, leaving the falciform ligament of the liver as the only remnant (Fig. 42-1B, C). Within the transverse septum (from which the diaphragm evolves), the liver forms and moves into the coelomic cavity, carrying an investment of peritoneum. The only attachments of the liver to the transverse septum are small portions of the peritoneum, which become the triangular and coronary ligaments (behind which are the "bare areas" of the liver).

The blood vessels (e.g., lymphatics) to the various developing viscera course the posterior or dorsal mesentery. The anterior attachment of the mesentery between the liver and the stomach, esophagus, and duodenum becomes the lesser omentum with two portions, the gastrohepatic and the gastroduodenal ligaments (Fig. 42-1B and C).

One might best understand the relationships of the pancreas to the omental bursa by considering the rotation of the bowel and changes in the dorsal mesentery. The pancreas forms from entodermal buds of the duodenum, the (ventral) anterior bud being slightly caudad but close to the common bile duct and the (dorsal) posterior bud being directly opposite to it. As the "C" loop of the duodenum

rotates, the two pancreatic buds come together and fusion occurs at the level of the head. The ventral segment remains as the uncinata and head portion. The spleen forms in the (dorsal) posterior mesentery and is carried laterally as the omental bursa forms. The dorsal mesentery containing the pancreas fuses with the posterior abdominal peritoneum (Fig. 42-1D). The multiple layers of the embryologic mesentery as it relates to the retroperitoneum, pancreas, and colon can be seen (Fig. 42-1D).

The lesser omentum and the omental bursa are formed by the rotation of the stomach and duodenum and the posterior movement of the pancreas (Fig. 42-1B and C). The anterior aspect of the bursa consists of the lesser omentum, composed of the hepatoduodenal and the gastroduodenal ligaments, the posterior wall of the stomach, the gastrocolic ligament, and the mesocolon. The posterior wall is bounded by the peritoneum over the top of the pancreas. (This peritoneum is on the right side of the dorsal mesentery, which is on the anterior surface of the pancreas.) The lateral wall consists of the gastrocolic, gastrosplenic, and splenorenal ligaments (Fig. 42-1C). The other boundaries of the omental bursa are described under the "Normal Peritoneal Anatomy."

As the bowel and the colon rotate, the mesentery of the mesocolon fuses posteriorly with the covering of the retroperitoneum (Fig. 42-1E). If the fusion is complete, the spaces remain intact and conform to the traditional anatomic concepts of the retroperitoneum and the peritoneum (i.e., the peritoneal space is the anterior space and has a number of different compartments).⁶⁵ Traditionally, the retroperitoneum is divided into three parts: the anterior pararenal, posterior pararenal, and perirenal spaces. After extensive CT experience, it has become apparent that the traditional concept does not always explain some observations. Dodds et al^{19, 20} have reviewed the embryologic formation of the retroperitoneum and proposed a new concept that reconciles some inconsistent observations.

Peritoneum

The peritoneum is a serous membrane covered with a single layer of mesothelial cells that envelops all portions of the abdomen. The total surface area is about 1.7 m², but the functional area (physiologic conditions described in the next section) is about 1 m².⁴² The cavity is closed except for the fallopian tubes and contains 50 to 75 mL of clear fluid, which has a specific gravity of 1.016, and fewer than 3000 cells/mm². The cells are lymphocytes,

Figure 42-1. Embryology of gastrointestinal tract.

A, Diagram shows the embryologic formation of the gut as the entodermal canal within the layers of the mesoderm and ectoderm. The entoderm is attached posteriorly by the dorsal mesentery and anteriorly by the ventral mesentery (arrow). The coelomic cavity (later to be the peritoneal cavity) is lined by mesodermal cells (later to be the peritoneum).

B, A later stage in the embryo shows the liver having formed in the anterior or ventral mesentery. This mesentery persists as the falciform ligament and the lesser omentum between the liver and the stomach. The spleen and dorsal pancreas form in the posterior or dorsal mesentery. A folding of the posterior mesentery and mesogastrium forms the omental bursa. The kidney and adrenal gland are located in the retroperitoneum. (According to Dodds et al., the space within the mesentery is and should continue to be called the intermesenteric space, regardless of any changes in configuration.)

C, This diagram approximates the adult configuration, with the liver having moved to the right. The rotation of the stomach, spleen, lienorenal ligament, and pancreas produces the margins of the omental bursa.

D, Adult retroperitoneal spaces at the level of the left kidney. The primary retroperitoneum is divided by the anterior renal fascia (dashed lines) and the posterior renal fascia (dotted lines) into perirenal and posterior pararenal spaces. The fusion of the anterior renal fascia to the primary dorsal peritoneum eliminates any anterior pararenal space. Ventral to the primary retroperitoneum, a secondary retroperitoneum forms, consisting of a pancreaticoduodenal space overlying a retroperitoneal colonic space. These secondary spaces are demarcated by folded, laminated leaves of mesentery that fuse with one another or the primary dorsal peritoneum. K, Kidney; L, left.

E and F, Schematics of retroperitoneal colonic space. K, Kidney; R, right; L, left. Right leaf of the mesocolon, long and short dashes; anterior perirenal fascia, short dashes; posterior perirenal fascia, dots; and lateral fascia, dots and dashes. E, Axial section through the pancreas of a 14-week-old human fetus. During colonic rotation (arrows), the left and right colon swing toward the flanks so their dorsal mesentery, or mesocolon, lies flat against the posterior abdominal wall. At this stage, the mesentery of the duodenum and pancreas has already fused with the posterior peritoneum to form the pancreaticoduodenal space. Thus, bilateral retroperitoneal colonic spaces come to lie ventral to pancreaticoduodenal space but extend more caudad. F, Depending on complete or incomplete fusion of these spaces (arrow), the pericolic space may be very shallow, extend slightly posteriorly (vertical arrow), or even medially into the fascia (horizontal arrow). These changes are only appreciated when ascites is present.

D and E, From Dodds WJ, Darweesh RM, Lawson TL, et al: The retroperitoneal spaces revisited: Pictorial essay. *Am J Roentgenol* 147:1155, copyright by American Roentgen Ray Society, 1986.)

macrophages, eosinophils, mast cells, and rare free mesothelial cells. The peritoneum is normally sterile and free of bacteria.

Peritoneal Function

The function of the peritoneum can be separated into fluid dynamics and particle clearance. The peritoneal membrane is a semipermeable membrane that permits bidirectional diffusion of water and solutes. Fluid and solute exchange are related to membrane area and permeability. The permeability and transfer of material depend on blood flow, vasoactive compounds, and tonicity of the peritoneal fluid (or osmotic pressure of blood).^{68, 119} Hyperosmotic fluid, inflammation, chemical irritants (bile, gastric acid, pancreatic fluid), or vascular agents can cause a net flow of water as high as 300 to 500 mL/hour into the cavity.^{43, 60}

Although the passive exchange of fluids and solutes occurs over the entire surface, the clearance of particulate material (e.g., bacteria, cellular metastases) is restricted to the diaphragmatic surface of the peritoneum.^{3, 4, 68} Through stomata between mesothelial cells, particulate material and fluid can be absorbed into specialized lymphatic vessels called *lacunae*.^{3, 4, 109, 111} The material is transported through the diaphragm and into the retrosternal and anterior mediastinal lymphatic vessels to the right thoracic duct; reverse

flow is prevented by lymphatic valves (Fig. 42–2).^{11, 46} The stomata have been shown to accommodate particles smaller than 20 μm in size (using polystyrene beads); the size varies with respiratory movement.

In conjunction with the active flow of fluid through the diaphragm, respiratory motion of the diaphragm, gravitational pull on the liver, and normal peristalsis of the bowel enhance the flow of fluid cephalad. Normal peristalsis displaces fluid to the lateral gutters where the upward flow occurs. The respiratory movement of the diaphragm creates a negative subphrenic pressure, which enhances upward flow (Fig. 42–3A). Also the gravitational pull on the liver creates a negative pressure above the liver that enhances the flow upward. The sum of these influences is generally an upward movement of fluid toward the diaphragm covered by the peritoneum with the lacunae as noted previously. The net result and influence can be seen in Figure 42–4A, B.

Anything that alters the normal pattern of respiratory motion or affects motility of the bowel inhibits this normal flow. An ileus created by a laparotomy or other problem delays clearance time of the peritoneum. Positive pressure ventilation, increased intra-abdominal pressure, or phrenic neurectomy alters the physiologic processes and movements and thereby impairs normal clearance.

Gravity also plays an important role in the flow of fluid and particulate material.^{7, 79, 114} The *in vivo* effects of gravity

Figure 42–2. Location of the lymph nodes that filter material from the abdomen. **A**, CT scan through the upper abdomen of a patient with abdominal inflammation shows enlarged lymph nodes below the surface of the diaphragm (arrows). **B**, Higher scan in the same patient shows enlarged lymph nodes in the anterior mediastinum in front of the pericardium (arrow). Lymphatic material enters the lacunae on the undersurface of the diaphragm and enters the lymphatics of the mediastinum. **C**, Later scan performed at the level of the liver shows the shrinkage of the lymph nodes after inflammation has resolved.

Figure 42-3. Peritoneal dynamics and physiology. A, Diagram showing the directions of fluid flow and clearance within the peritoneum. The relative size of the arrows indicates the relative contribution from each area. B, Pathogenesis of peritoneal adhesions. C, Diagram of bacterial interaction with the immune systems, and their clearance mechanisms. PMN, polymorphonuclear neutrophils; RES, reticuloendothelial system.

on particle distribution were studied by looking at clearance of contrast material injected into peritoneal cavities after routine appendectomy and cholecystectomy. Material injected into the ileocecal region goes preferentially to the pelvis, right paracolic area, and right subhepatic area. A smaller amount passes to the left pericolic gutter and the left subhepatic space. Material injected into the right subhepatic space next to the duodenum spreads to the right subphrenic space, the left infrahepatic space, the right pericolic gutter, and the pelvis (see Fig. 42-3). The infracolic

spaces were not involved in either case, even when contrast material was injected into the ileocolic region, probably because the net flow of fluid is from the bowel loop surfaces laterally, as noted previously.

Response to Infection

There are two effective defensive mechanisms against pyogenic infections in the peritoneum: the mechanism of

Figure 42-4. Fluid flow in peritoneum. **A**, This radiograph was taken after the injection of contrast material through a T-tube tract (C), which was displaced from the common bile duct and into the subhepatic recess. The edge of the right lobe of the liver (*large arrows*) is seen. The falciform ligament (*curved arrow*) is surrounded by contrast material. Contrast material flows to the left side into the anterior portion of the left subdiaphragmatic space (*arrowheads*) adjacent to the stomach. Some material has entered the omental bursa (*small arrows*) through Winslow's foramen. (The patient is rotated because of scoliosis.) **B**, In this later radiograph, contrast material is better seen in the subhepatic recess (Morison's pouch) (*arrowheads*). It flowed cephalad into the right subdiaphragmatic space (*large arrows*). The impression of the kidney on the subhepatic recess is seen (*small arrow*). (The space appears to be located more medially because of the patient's rotation.) The left subdiaphragmatic space is also seen (*open arrows*).

particulate clearance^{68, 78, 119} and the typical immune response (involving antibodies and white cells) (see Fig. 42-3B). Absorption of bacteria into the diaphragmatic lymphatic system permits eradication of the bacteria by the systemic defense mechanisms of fixed tissue macrophages, reticuloendothelial cells, and polymorphonuclear leukocytes.^{36, 37} Laboratory models have shown that bacteria begin to disappear from the peritoneum even before the influx of phagocytic cells. In such cases, bacteria have been isolated from mediastinal lymph channels within 6 minutes from the time of peritoneal injection.

The attraction of phagocytes, which can lyse bacteria, into the peritoneum¹⁰⁴ occurs by chemotaxis (see Fig. 42-3C). Chemotaxis occurs after activation of various complement components and attraction of phagocytes.⁷ Killing of the bacteria with intracellular chemicals occurs after phagocytosis. Ingestion by phagocytes may occur unaided, but at times opsonization by complement (C3) or immunoglobulin G (IgG) may be required with encapsulated organisms.¹⁰⁵

Fibrin also serves as a local defense mechanism, which is useful in one regard but detrimental in others. With peritoneal injury, a release of histamine and other perme-

ability factors that may permit leakage of a protein-rich material containing fibrinogen occurs. This material, combined with tissue thromboplastin, causes the polymerization of fibrin. Normally, fibrin may be split and removed as needed by the activation of plasminogen to plasmin; however, when injury to the mesothelium or peritonitis occurs, no fibrinolytic activity takes place.^{40, 119}

Although fibrin localizes the pathogens to a nearby area instead of permitting them to spread, it impairs eradication of the bacteria.^{65, 119} Fibrin hinders the clearance of bacteria into the lymphatic system. Fibrin also protects the bacteria from phagocytic activity and impairs exposure to antibiotics.^{37-39, 80} This latter problem is being addressed in percutaneous abscess drainages by the use of fibrinolytic agents (see "Abscesses" later).

An abscess occurs when further tissue destruction results from enzyme release from the phagocytes and bacteria. Further growth of the bacteria and mobilization of the immune system may rarely eradicate the abscess, or it may progress with more inflammation and destruction. Once a large inoculum of bacteria is established in an abscess, a low oxidation potential results³⁷ and impairs phagocytosis and antibiotic activity. In most cases, drainage is required.

Normal Peritoneal Anatomy

Because of the extensive work and educational efforts by Meyers⁷⁹ and Whalen,¹¹⁴ knowledge of the anatomic spaces has become widespread among the radiologic community. I have relied heavily on these sources for the information in this chapter, but I have also drawn on additional physiologic data and clinical experience. The general orientation of the anatomy can be appreciated by studying radiographs with contrast injection delineating the perihepatic spaces (see Fig. 42-4A and B).⁹³

Normal anatomy in this chapter is shown in axial, coronal, and sagittal images provided by thin sections from a new multislice scanner. Using 1-mm sections and subsecond scanning, these reconstructions show remarkably accurate anatomic relationships (Figs. 42-5 to 42-7; see Fig. 42-4).

Supracolic and Infracolic Spaces

The peritoneal spaces are potential spaces that are not normally visualized unless they are distended with fluid or unless the fascia is thick.

The abdomen can be divided into the supracolic, infracolic, pericolic (pericolonic), and pelvic spaces. The supracolic and the infracolic spaces are separated by the transverse colon and its mesentery (see Figs. 42-5B and C, 42-6D, and 42-7A-D). Anteriorly, the greater omentum is located between the peritoneal wall and the bowel (see Figs. 42-6E and 42-7D).

The supracolic spaces include the perihepatic spaces and the omental bursa. The infracolic space is divided into the right and left spaces by the root of the mesentery, which extends right to left from Treitz's ligament to the ileocecal area. Laterally, the pericolonic gutters communicate with the perihepatic spaces and the pelvic region.

Perihepatic Spaces

The perihepatic spaces consist of the subphrenic (subdiaphragmatic) spaces and subhepatic spaces. There are right, left, anterior, and posterior spaces in each area.

The right subphrenic space is continuous with the right subhepatic space and the right pericolic space. The right subphrenic space lies adjacent to the lateral and superior portion of the liver between the diaphragm and the body wall (see Figs. 42-5A-C, 42-6A-C, and 42-7). On axial and coronal images, the posterior margin of the subphrenic space ends at the anterior edge of the coronary ligaments (which encompasses the bare area of the liver against the posterior surface of the abdominal cavity) (see Figs. 42-5C and D, 42-6A, and 42-7A).

The right subphrenic space is limited medially by the falciform ligament (see Fig. 42-6A) in the upper portion of the abdomen. Because of variability in size, the ligament may or may not serve as an effective barrier to the spread of material to the left side (see Figs. 42-5A and 42-6A).

The left subphrenic space is beneath the left diaphragm and surrounds the fundus of the stomach anteriorly, the spleen, and the space between the liver and the stomach (see Figs. 42-6A-D and 42-7D). Fluid can also be localized into various areas of the space (e.g., anterior, poste-

rior). The left subhepatic space is immediately continuous with the anterior part of the left subphrenic space (see Figs. 42-5B and 42-6A and B). The lateral perisplenic portion is immediately continuous with the left pericolic space (see Fig. 42-6D). Although it is traditionally taught that the phrenicocolic ligament restricts flow of material from the left pericolic space to the left subphrenic space, in reality, it seldom is an effective barrier (see Fig. 42-5A and B). CT scans in numerous patients have shown variability in size, shape, and location of the ligament, which explains the inconsistent performance of the ligament as a barrier to infection.

The subhepatic spaces consist of a right subhepatic and a left subhepatic space (see Figs. 42-5A, 42-6B, and 42-7A and D). The right subhepatic space is adjacent to the gallbladder and extends posteriorly back to the anterior surface of retroperitoneum over the right kidney (see Figs. 42-5A and C, 42-6D, and 42-7A). It is immediately adjacent to the duodenum and Winslow's foramen, whose anterior edge consists of the edge of the lesser omentum, which contains the hepatic artery, portal vein, common bile duct, and lymph nodes (virtually all nodes from the perihepatic area—except the lower portion of the colon—converge at this area) (see Figs. 42-5B, 42-6B and C, and 42-7B and C).

The left subhepatic space is the space immediately beneath the left lobe of the liver and is continuous with the anterior part of the left subphrenic space (see Figs. 42-5A, 42-6A, and 42-7D). It is bounded posteriorly by the lesser omentum and on the sides by the capsular surface of the left liver lobe and the stomach.

The omental bursa (lesser sac)¹⁹ is behind the stomach and anterior to the pancreas (see Figs. 42-5A and B, 42-6B and C, and 42-7B and C). The left margin is the gastrosplenic (gastrosplenic) ligament, and the anterior margin is the gastrohepatic ligament; the right margin is the medial surface of the coronary ligament and the edge of lesser omentum, which is the boundary of the superior recess. The caudal boundary of the omental bursa is the gastrocolic reflection and the mesocolon. The greater omentum extends caudad from the anterior edge of the fundus of the stomach and the gastrocolic ligament. It contains a potential space in the fused membranes that may be split into a true space by an active process (i.e., bleeding or infection). The omental bursa can be divided into an inferior and superior recess of the omental bursa by the reflection over the left gastric artery (see Figs. 42-5A and B and 42-6A-C).

The superior recess is a potential space in the right side of the omental bursa and is seldom seen in patients with a transudative effusion. In cases of pseudocysts, infection, or processes that incite a pressure phenomenon, it may be visualized. The margins of these spaces are variable from one patient to another and may extend high beside the caudate lobe, vena cava, and into the porta hepatis (see Figs. 42-6A and 42-7C).

Pericolic Spaces

The right and left pericolic spaces are spaces that are contiguous with the pelvic region and the subphrenic spaces (see Figs. 42-5A-C and 42-6E-G). These spaces receive flowing fluid displaced from around the small

Text continued on page 1621

Figure 42-5. Peritoneal spaces in three dimensions. **A**, Coronal image of the anterior abdomen in a patient with dilute contrast material injected into the peritoneum. The various portions of the peritoneal cavity can be identified. The right subphrenic space (RSP) extends from the falciform ligament (F) laterally between the abdominal wall and the liver. This space then communicates with the pericolic space (RC) and the right subhepatic space (RS). The right pericolic space flows into the right side of the pelvis. The left subphrenic space (LSP) communicates with the left subhepatic space (Lsh). Flow from these spaces is limited caudally by the phrenicocolic ligament (PCL). The left pericolic space (LC), extends caudally into the left side of the pelvis (LP). In the region of the suprahepatic spaces, the right subhepatic space (RS) is below the right lobe of the liver and extends into the lesser sac (vertical down arrow) beneath the edge of the lesser omentum, which contains the portal vein, hepatic artery, and common bile duct. This is immediately adjacent to the pancreas (P). The upper margin of the lesser sac is bounded by the gastrohepatic ligament (gh) containing the gastric vessels. The mesentery (M) is noted in the midline containing the mesenteric vessels.

B, Coronal scan of a patient with dilute contrast in the peritoneum. The peritoneum is generally divided into supracolic and infracolic (RI) spaces by the mesocolon (horizontal arrow), which extends from the anterior margin of the pancreas (P). The supracolic space encompasses all of the subphrenic, perihepatic, and perisplenic spaces. The right subphrenic space extends from the upper space below the diaphragm (oblique arrow) and laterally around the liver (RSP). The falciform ligament is not seen, which demonstrates why it may not always serve as a complete barrier between the right and left sides. The subphrenic space communicates with the right pericolic space (RC), which extends into the right pelvis. The right subphrenic space communicates with the right subhepatic space (horizontal arrow) (see Fig. 42-4B), which is adjacent to the gallbladder (g) and duodenum (D). This space extends into the lesser sac (L) under the hepatoduodenal ligament (HD), which contains the portal vein, hepatic artery, and common duct. The lesser sac continues behind the stomach (ST), which is better seen on the sagittal views to follow. The superior boundary is the gastrohepatic ligament (gh). The left subphrenic space (LSP) is located below the diaphragm, around the left lobe and the stomach. It is limited inferiorly by the phrenicocolic ligament (pcl). The left pericolic space (LC) extends into the pelvis.

Figure 42-5 Continued. C, Coronal image more posterior than B. This level demonstrates the attachment (arrows) of the coronary ligaments of the right liver (straight arrows) to the more posterior portion of the diaphragm and abdominal cavity. The communication of the right subphrenic space to the pericolic (RC) and right subhepatic space (RS) is well seen. The broad attachment of the mesentery located on the posterior abdominal wall extends from the ligament of Treitz (upward curved arrow) to the right lower quadrant (curved arrow). The recesses of the lesser sac, the superior recess (S) adjacent to the vena cava (v), and the splenic recess (SP) behind the stomach are seen. Aorta (A) is noted. The phrenicocolic ligament (pcl) is again noted in the midportion of the left pericolic space (see Fig. 42-4B). The mesentery of the small bowel (M) and the iliopectus muscles (P) are seen. Contrast material in the pelvis is also noted.

D, Posterior coronal section shows the retroperitoneum and posterior portions of the peritoneum. The most posterior portions of the liver (L) and spleen (S) have medial and posterior "bare areas." Note the contrast material in the most posterior portions of the right and left subphrenic spaces (horizontal arrows). The retroperitoneum contains the right (RK) and left (LK) kidneys, which are surrounded by a cone-shaped space containing fat. The highest extent of the pararenal spaces extends cephalad under the diaphragm, contains the adrenal glands, and merges with the bare areas. The iliopectus muscles (P) extend distally and merge with the iliopectus muscles (IP).

Figure 42-6. Coronal images of peritoneum. A, Axial scan through the upper abdomen shows the perihepatic spaces in the supracolic region. The right subphrenic space (rsp) extends from the falciform ligament (F), anteriorly around the liver and posteriorly to the coronary ligaments (cl). Behind these ligaments is the "bare area" of the liver, which is the most cephalad portion of the retroperitoneum. The left subphrenic space (lsp) extends posteriorly around the left lobe of the liver, stomach, and spleen. At this high level, the peritoneal space surrounds the spleen on all surfaces; the attached bare area of the spleen is attached posteriorly at the level of the splenic pedicle (see C). The left subhepatic space is contiguous with the left subphrenic space. Also at this level, the superior recess (arrows) of the lesser sac is seen around the caudate lobe of the liver (C). The splenic recess (r) of the lesser sac is noted behind the stomach (ST). The gastrohepatic ligament and the gastrosplenic ligament (gs) are noted.

B, This axial scan is at a slightly lower level over the lesser sac. The right subphrenic space (rsp) is noted lateral to the liver; inflammatory processes may sequester collections into anterior and posterior components. The left subphrenic space can be subdivided into the anterior (alsp) and posterior (plsp) spaces, and it ends posteriorly at the bare area of the spleen. The anatomic boundaries of the lesser sac are noted. The sac (L) is anterior to the pancreas (P) and extends posteriorly behind the stomach (S). The margin of the foramen of Winslow (w) contains the portal vein, the hepatic artery, and the common bile duct. The classic boundary within the lesser sac is the left gastric artery, which resides in the gastrohepatic ligament (vertical arrow) and the gastrosplenic ligament (gs). This peritoneal reflection over the gastric artery divides the inferior and superior components of the lesser sac. At this level, the spleen has a retroperitoneal component, which begins at its posterior margin (arrow). The retroperitoneum around the kidney consists of several planes (see Fig. 42-1).

C, Axial scan at the level of the pancreatic head shows the perihepatic spaces, as noted in A and B, as well as additional peripancreatic anatomy. The inferior portion of the lesser sac (L) is anterior to the pancreas. The right subhepatic space (RS) is behind the gallbladder (g). The anterior boundary consists of the gastrohepatic ligament (horizontal arrow pointed left). The head of the pancreas (P), superior mesenteric artery (sma), left lobe of the liver (LL), and air-filled duodenum (D) are seen.

Illustration continued on following page

Figure 42-6 Continued. *D*, Axial scan at lower level than *C*. At this level, the right subphrenic space (rsp) merges with the posterior right subhepatic space (RS) (also known as Morison's pouch). The left subphrenic space (lsp) also begins to merge with the left pericolic space at this level. The left infracolic space (LIC) is seen to the left of the mesentery (M) and head of pancreas (P). The stomach is anterior and the greater omentum (arrows) lies anteriorly on either side. The kidneys (K) and spleen (S) are noted.

E, Axial scan at level below *D*. The right subphrenic space lateral to the liver converges with the right pericolic space (RC) adjacent to the cecum (C). The left pericolic space (LC) is on the left. The right infracolic space (RIC) adjacent to the mesentery (M) and the left pericolic space (LC) are noted. The fat-density greater omentum (arrows) is noted in the anterior peritoneum.

F, Lower axial scan shows the upper pelvis. The right (RC) and the left (LC) spaces are noted; the right space is lateral to the cecum (CE). The psoas muscles (P) are noted posteriorly, medial to the retroperitoneum below the renal fossa.

Figure 42-6 Continued. *G*, Axial scan in the pelvis shows communication of the pericolic spaces into the pelvis. Perirectal spaces (*horizontal arrows*) are lateral to the rectosigmoid (RS).

H, Scan taken through lowest part of pelvis, showing perirectal spaces.

bowel and are bounded laterally by the peritoneum of the abdominal wall and medially by the peritoneum over the colon. The depth and configuration of these spaces may vary, depending on the completeness of the fusion of mesentery in the embryologic state. The pericolic space may in such cases extend posteriorly, adjacent to the kidney.⁹⁷ The posterior extension occurs most commonly on the right side, which accounts for the observation that the right paracolic space is deeper than the left. This common variation has prompted new theories about the retroperitoneal spaces (see “New Concepts of Retroperitoneum and Peritoneum” later).

If a portion of the colon, such as the splenic flexure, is not in the normal location, the configuration of such spaces may be difficult to predict. Regardless of the anatomic variation, however, one can be confident that CT accurately displays the precise pathologic anatomy (even if there is some controversy about the nomenclature).

Infracolic Spaces

The right and left infracolic spaces are separated by the mesentery, which extends from Treitz’s ligament in the left

upper quadrant to the ileocecal region in the right lower quadrant (see Figs. 42-5B, 42-6D, and 42-7A and D). The left infracolic space communicates with the lower portions of the abdomen, but the right infracolic space is confined by the mesocolon, ascending colon, and the posterior attachment of the mesentery.

Pelvis

The right pericolic, left pericolic, and left infracolic spaces have pathways into the pelvis. On the left side, the mesentery of the sigmoid provides a surface on which neoplastic or inflammatory processes may center (see Fig. 42-5A and B). In addition, the broad ligaments of the uterus create a surface on which processes become involved.

From an anatomic standpoint, the pelvis can be subdivided into an anterior portion, which has certain fossae common to both men and women, and a posterior portion, which has some differences between men and women. The anterior divisions are less consistently visualized, depending on individual anatomy (Fig. 42-8; see Fig. 42-6H).

Figure 42-7. Sagittal images of peritoneum. **A**, Sagittal scan to the right of midline. The anterior right subphrenic space (rsp) is seen anterior to the liver, and the right subhepatic space (RS) is below the right lobe. The posterior attachment of the phrenic space limits the space posteriorly (*curved arrow*). The duodenum (D) and the upper portion of the hepatoduodenal ligament (*vertical arrow*) are noted adjacent to the subhepatic space (RS). Also noted are the hepatic flexure (HF) of the colon, the right kidney (RK), the infracolic space (IC), and the sigmoid colon (SC).

B, Sagittal scan slightly lateral to midline. The liver (RL), the anterior right subphrenic space (arsp), and the infracolic space (RI) are seen. The area of the foramen of Winslow (F) at the entrance of the lesser sac is noted. The lesser sac is limited posteriorly by the pancreatic head (PH), inferiorly by the transverse mesocolon (M), and anteriorly by the hepatoduodenal ligament (*arrow*). The portal vein (pv) is in the margin of the ligament.

The anterior pelvis is divided into several smaller fossae by peritoneal ligaments over certain vestigial remnants. These include the suprapubic fossa in the midline, bounded laterally by reflections over the closed umbilical arteries. The medial umbilical fold, which reflects over the vestigial remnant of the urachus, is in the midline of this space. Immediately lateral to these reflections, the medial inguinal fossa can be seen on the right and left; they are bounded laterally by the reflection over the inferior epigas-

tric arteries. Lateral to these are the lateral inguinal fossae, which are lateral to the inferior epigastric arteries. There is little clinical significance of these spaces except to distinguish between direct inguinal hernias, which are lateral to the epigastric artery, and indirect inguinal hernias, which are medial to the epigastric artery.

The posterior pelvic space is divided into areas that are determined by gender. In women, there is a space between the uterus and the bladder called the *vesicouterine space*.

Figure 42-7 Continued. C, Sagittal image close to midline. The liver (LL) and adjacent structures are seen, including the anterior left subphrenic space (alsp), the superior recess of the lesser sac (small arrow), and the "bare area" of liver (horizontal arrow). The lesser sac (L) is seen bounded anteriorly by the edge of the gastrohepatic ligament and the hepatoduodenal ligament containing the duodenum (D), posteriorly by the pancreas (P), and inferiorly by the mesocolon (M). The aorta (A), with the celiac artery (C) and the superior mesenteric artery (sma), is seen.

D, Sagittal section to the left of midline. The left lobe of the liver (LL) is attached by the triangular ligaments to the diaphragm (curved arrow). The anterior left subphrenic space (alsp) is in front of the liver; the left subhepatic space is between the liver and the stomach (ST). The splenic recess (SP) is behind the stomach, in front of the spleen (S) and the pancreas (P). The splenic artery and vein (av) are seen in the hilum. The mesocolon (vertical arrow), with the splenic flexure, is seen, clearly separating the supracolic and infracolic spaces. Anteriorly, the greater omentum (horizontal arrows) is seen extending from the margin of the stomach.

The rectouterine space is between the uterus and the rectum. The spaces on each side of the rectum are called the *right* and *left pararectal spaces*. Some have also designated an ovarian fossa adjacent to the ovaries.

Men have fewer spaces in the pelvis, the rectovesicular space, and the right and left pararectal spaces. There is no space associated with the prostate, which is below the bladder.

In women, the ovarian fossae and vesicouterine space vary according to the size, configuration, and angulation of the uterus. The right and left pararectal spaces may also

vary in size. In some patients, the right side may predominate with no space on the left. In other patients, the pararectal spaces may extend posteriorly around the rectum and extremely low, almost to the level of the coccyx.

Retroperitoneum

Traditionally, the retroperitoneum is said to have different compartments, depending on the level. At the level of the kidney, the space behind the peritoneum can be divided

Figure 42-8. Axial scan through the female pelvis shows the uterus (U), rectum (R), and the rectouterine space (RU). The tubes and broad ligaments extend laterally.

into the anterior pararenal, the perirenal, and the posterior pararenal spaces (Fig. 42-9; see Fig. 42-1D and E). The division of this space is made based on the perirenal fascia. Gerota's fascia is the posterior portion, and Zuckerkindl's is the anterior one. The anterior pararenal space is bordered anteriorly by the peritoneum on the retroperitoneum, posteriorly by the anterior perirenal fascia, and laterally by the lateroconal fascia. The perirenal space is the space around the kidney bordered anteriorly by the renal fascia and the posterior renal fascia. The posterior pararenal space is bordered anteriorly by the posterior renal fascia and posteriorly by the fascia over the psoas muscle, which is continuous with the transversalis fascia.

Below the level of the kidneys, the retroperitoneal spaces are a single space with direct contiguity between the anterior and the posterior portions.

The cephalic and caudal relationships of the spaces should also be discussed. The perirenal space is the shape of an inverted cone (open at the bottom and closed at the top) (see Figs. 42-4, 42-5D, and 42-7A). The cone is attached superiorly to the diaphragm, whereas the open end of the cone is open to the pelvis. Both the anterior and the posterior pararenal spaces extend into the pelvis and cephalad to the level of the diaphragm. On the right side, the upper extent of this space is the bare area of the liver, and on the left, it is the bare area of the spleen. With certain pathologic processes, the mediastinum can communicate with either of these areas.

New Concepts of Retroperitoneum and Peritoneum

With the extensive experience gained with CT over the years, it has become apparent that the traditional description of the retroperitoneum and the posterior portions of the peritoneum does not fit some observations that have been made.

The inconsistencies of the traditional approach have related predominantly to the relationship of the anterior pararenal space to the retroperitoneum and the peritoneum.^{20, 92} Authors have noted that the lateroconal fascia is not constant in its location and does not really function as a barrier to the spread of fluid or inflammation. Fluid from the pancreas region does not always spread to the margins of the colon, which are supposedly in the same space.

After reviewing the embryologic information, Dodds and colleagues^{19, 20} came to several conclusions that differed from the traditional description. During embryologic development, the gut and its derivatives form in the intermesenteric space; they remain in this space regardless of any migration, folding, or fusion. Communication between the various components of the intermesenteric space follows the areolar connective tissue (the course of which can be followed by noting the vasculature) (see Fig. 42-1B-D). Communication between the retroperitoneum and the intermesenteric space is therefore only by means of spaces along the vessels predominantly at the root of the mesentery. A number of rotations and fusions occur before the adult form results. With the rotation of the bowel, the ventral pancreas and dorsal pancreata come to fuse and, with the duodenum, lie against the embryologic peritoneum. Fusion of the left side of the dorsal mesentery and the retroperitoneal embryologic peritoneum occurs at a line that the traditionalists have called the *anterior renal fascia* (see Fig. 42-1D, E), which Dodds et al²⁰ have called the *retropancreatic peritoneal recess*. It has been given this name because it represents a potential space that can be "split" by certain pathologic processes in the area.⁹

At about this time, the colon rotates and the mesocolon fuses to the mesentery over the pancreaticoduodenal space and laterally to the posterior parietal peritoneum (see Fig. 42-1E). Most commonly the fusion is complete and extends from the ascending colon and the cecum on the right to the descending colon by the sigmoid on the left (see Fig. 42-1A-G). If fusion is complete, the right and left colon are "sandwiched" between the flattened pancreaticoduodenal space and the retroperitoneum. If the fusion is not complete, a variation in the spaces results.

Without complete fusion, the colon has a mesentery (cecum or right colon in 10% to 20% of cases) and there is no colonic retroperitoneal space. When this occurs in some cases, the splenic flexure can occasionally be located medial to the spleen. In the adult, the distribution of ascitic fluid in the paracolic gutter depends on the shape of the recess and the extent of fusion of the mesocolon with the retroperitoneum. Without fusion, fluid or bowel can go posterior to the kidney by the psoas muscles.

When this approach is used, the compartments of retroperitoneal spaces differ. The anterior renal fascia fuses with the primordial peritoneum over the retroperitoneum (thus, there is no anterior pararenal space). The posterior renal fascia fuses posteriorly with the fascia over the psoas and quadratus lumborum muscles. Laterally, it fuses with the peritoneum, which extends anteriorly inside the peritoneal fat.

The cephalic and caudal boundaries also differ in the new concept. First, below the level of the renal fascia, there are two separate spaces (anterior and posterior), which are different areas of the intermesenteric space and do not

Figure 42-9. Schematic of retroperitoneal spaces based on the traditional concept of retroperitoneal anatomy. K, Kidney; PM, psoas muscle. Anterior (*dashed*) and posterior (*dotted*) perirenal fascia join to form lateroconal fascia (*dot-dashed*). These fasciae divide the retroperitoneum into (1) the anterior pararenal space that contains the duodenum, pancreas, and right and left colon; (2) the perirenal space that contains the kidney and adrenal gland; and (3) the posterior pararenal space that contains fat. A, Axial section of the pancreas. B, Axial section of the left upper quadrant just caudal to the pancreatic tail. The anterior pararenal space is subtended ventrally by the posterior peritoneum and dorsolaterally by the anterior renal fascia and lateroconal fascia. The posterior pararenal space is demarcated ventrally by the posterior perirenal fascia and lateroconal fascia and dorsolaterally by transversalis fascia. C, Parasagittal section through the right kidney. The bare area of the liver is in continuity with the anterior pararenal space. The posterior pararenal space communicates with the anterior pararenal space in the iliac fossa, below the perirenal space. (See Fig. 42-1D-F, for an explanation of the newer concept.) (B, From Dodds WJ, Darweesh RM, Lawson TL, et al: The retroperitoneal spaces revisited: A pictorial essay. *Am J Roentgenol* 147:1155, 1986. Copyright by American Roentgen Ray Society, 1986.)

communicate directly. The anterior space contains the vessels of the sigmoid and ascending colon. The posterior space contains the retroperitoneal structures. The cephalad relationships also change. The anterior renal fascia is said not to extend above the adrenal glands; the bare area of the liver and spleen would then correspond to the posterior pararenal space.

The new approach can be summarized as follows. The previously designated anterior pararenal space is called the *intermesenteric space*, which is separated into two compartments, one for the colon and one for the pancreas and the duodenum. Communication between the different components, such as the pancreaticoduodenal and the colonic intermesenteric space, is along the vessels. When fusion of the mesothelium is not complete, there may be separation of the potential spaces by pathologic processes. With pancreatitis, for example, the primordial space splits with inflammatory fluid (which looks like the splitting of what was previously called the *anterior pararenal space*).^{9,78} The depth of the paracolic spaces can vary posteriorly, and the position of colic mesentery can vary, depending on fusion of mesentery. The retroperitoneum

above and below the cone of Gerota's fascia varies from the traditional viewpoint because there is only a posterior pararenal space (no anterior spaces).

Peritoneal Reflections or Ligaments

The various "ligaments" of the peritoneum are actually peritoneal reflections over tissue containing areolar tissue, arteries, veins, lymphatics, vessels, and lymph nodes. The margins of the ligaments are not definable except when the edges of the peritoneum are seen because of fluid or contrast material.

Understanding the reflections is important because they serve as boundaries to the peritoneal spaces and also as possible conduits for the contiguous spread of inflammation or neoplasms. These ligaments have been discussed under the category of the subperitoneum at various material meetings.

Coronary and Triangular Ligaments

The coronary and triangular ligaments represent attachments between the liver and the parietal peritoneum over

the abdominal wall. The coronary ligaments are contiguous with the capsule of the liver and attach the right lobe of the liver to the posterior abdominal wall (see Figs. 42-5D, 42-6A and B, and 42-7A and B). The triangular ligaments (Fig. 42-7D) are extensions of Glisson's capsule and attach the left lobe to the diaphragm. Although they are typically called *suspensory ligaments*, it is not clear what mechanical support they really provide. The triangular ligaments are virtually never seen on CT scans, unless air is in the peritoneum, which highlights their margins. Although typically one thinks of the peritoneum and its spaces as completely constant, congenital variations may also occur. Authors have noted considerable variation in the size and position of the triangular ligaments.

Both sets of ligaments have little involvement with intra-abdominal processes except that they provide boundaries for the subphrenic and the right subhepatic spaces. When a retroperitoneal process occurs on the right side, it may extend into the bare area of the liver behind the right coronary ligaments or cross from one side to the other.

Falciform Ligament

This is a vestigial remnant that represents a peritoneal reflection (see Figs. 42-5A and 42-6A) over the closed umbilical vein, which remains as the ligamentum teres. In inflammatory disease of the pancreas, inflammation can extend along the fascial tissues around the porta hepatis, around the ligamentum teres, and to the abdominal wall. In patients with portal hypertension, the ligamentum teres may recanalize, resulting in a patent umbilical vein, which courses to the abdominal wall.

Finally, in the presence of tumors, such as ovary, stomach, colon, and pancreas, the falciform ligament may be a site of peritoneal seeding or extension. The normal ligament is not seen on CT scan unless free air or fluid within the abdomen provides better visualization.

Gastrohepatic, Gastrosplenic (Gastrolial), and Gastrocolic Ligaments

These three ligaments are in direct contiguity with the margins of the stomach. They provide the peritoneal boundaries of the omental bursa in conjunction with the peritoneal surfaces of the hilum of the liver,⁸ the posterior wall of the stomach, and the parietal peritoneum over the retroperitoneum. Because they contain the arteries, veins, lymphatics, vessels, and lymph nodes, they are conduits for the contiguous spread of disease.

A neoplasm beginning in the stomach can spread through any of these pathways into the lymph nodes along corresponding vessels (Fig. 42-10). Spreading may occur along the left gastric artery and coronary vein in the gastrohepatic ligament, along the celiac trunk and base of the hepatic artery in the hepatoduodenal ligament, along the gastrophiploic and short gastric vessels in the gastrosplenic ligament, and along the gastrophiploic vessels in the gastrocolic ligament.

Tumor involvement in the gastrohepatic ligament produces impression or impingement on the lesser curvature of the stomach. Involvement of the gastroduodenal ligament produces impingement on the stomach antrum. Gastrosplenic involvement shows pressure on the greater curva-

Figure 42-10. Scan of a patient with a single metastatic deposit in the gastrosplenic ligament (arrow).

ture of the stomach, and gastrocolic involvement produces changes on the upper portion of the colon. Conversely, processes that begin in the colon can spread to the stomach by these pathways. Processes from the duodenum or pancreas can spread along the hepatoduodenal ligament.

Extension within these various ligaments can also occur in some cases of pancreatitis or hemorrhage. The fluid may dissect within the ligaments and may even extend to the subcapsular areas.

Phrenicocolic Ligament and Mesocolon

The mesocolon attached on the anterior surface of the pancreas has a lateral attachment on the left side called the *phrenicocolic ligament*. The mesocolon containing the various colic vessels and lymph nodes can also serve as a pathway for disease. Spread of inflammation or neoplasms from the colon to the pancreas is possible by either of these paths.

Splenorenal (Lienorenal) Ligament

The splenorenal ligament is the connection between the spleen and the kidney. It contains the tail of the pancreas, the splenic vessels, and small vessels to the retroperitoneum. They are of little significance except as a landmark to distinguish between peritoneal and pleural fluid. Tumor can spread, and systemic portal collaterals can develop in this space.

Ileocolic Ligament

Mesentery at the ileocolic region may serve as a site for tumor implantation. Occurrence of this is infrequent (Fig. 42-11).

Sigmoid Mesentery

The mesentery of the sigmoid colon in the left lower quadrant acts as a barrier or a margin along which processes can collect. At times, it serves as a medial or caudal boundary for the spread of material down the left pericolic space (Fig. 42-12).

Broad Ligaments and Cul-de-Sac

The broad ligaments and cul-de-sac represent two low peritoneal reflections that border the lower portions of the

Figure 42-11. Patient with carcinoma of the pancreas has metastatic implant (arrow) adjacent to the ileocecal valve by the cecum.

cavity (see Fig. 42-8). Tumors within the peritoneal cavity can seed to either location; most commonly, ovary, colon, or gastric tumors involve these areas.

Mesentery

The small bowel mesentery containing the superior mesenteric vessels extends from the left upper quadrant at Treitz's ligament to the right lower quadrant at the ileocecal valve (see Figs. 42-5C, 42-6D, and 42-7C). It serves as a dividing point between the right and the left infracolic spaces.

Specific areas of the mesentery should be noted because they show changes with pathologic processes. These areas are the neurovascular bundles, the root of the mesentery, and the margin of the small bowel. Normally the neurovascular bundles are quite thin and are barely perceptible as thin lines within the fat-density mesentery (see Figs. 42-5C and 42-6D). The mesentery as a whole shows fat density and normally extends quite high into the abdomen, permitting the small bowel loops to appose themselves closely to the anterior abdominal peritoneum.¹⁰¹ The margins of the

Figure 42-12. Two metastatic implants (arrows) on the right and left side of the sigmoid mesentery.

fat on the inner surface of the small bowel are typically poorly defined because the course of the bowel is quite irregular and overlapping. When pathologic processes occur, the bowel dilates, the wall thickens, and the peristaltic motion lessens. Because the margins are more tuberlike, they are better defined and the junction between the mesentery and the bowel wall is better seen (see "Inflammatory Processes"). Retroperitoneal, mesenteric, and peritoneal processes can produce changes along the mesentery.¹¹⁵

Greater Omentum

The greater omentum originates along the margin of the greater curvature of the stomach and can cover a broad expanse of the anterior abdominal wall. The function and role of the greater omentum is not really defined, but removal does not produce any adverse effects in peritoneal function.

The normal omentum is usually imperceptible on routine scan. It is visualized only when fluid is present (see Figs. 42-6D, E and 42-7D) or it is pathologically involved. Two signs that can be helpful are the density of the omentum and the location of small bowel loops. The normal omentum shows fat density and is not seen; when it has infectious processes or neoplasms, it increases in density and becomes thicker and therefore can produce a mass effect on the small bowel loops.

Peritoneal Fluid and Peritonitis

Ascitic fluid occurs whenever there is active formation of peritoneal fluid or interference with its removal. It can be caused by anything that produces inflammation, venous obstruction, lymphatic obstruction, or albumin deficiency, including liver failure, caval or portal vein obstruction, infection, and neoplasms. Ascitic fluid can be detected quite well with CT, and with certain diseases, some specific ancillary findings may be provided to suggest the origin of the ascitic fluid (Fig. 42-13). For example, in patients with cirrhosis, there may be associated findings in the liver.

Figure 42-13. CT scan shows a fatty liver, which has a perihepatic fluid collection. It is difficult in some cases to see the adjacent fluid next to the liver capsule (arrows).

Figure 42-14. CT scan taken through the level of the subphrenic space shows the most posterior extent of the right subphrenic space (arrow) containing fluid. Its relationship to the adjacent bare area of the liver (L) containing the kidney (curved arrow) and the pleural space is well visualized.

Similarly, with pancreatitis, there may be enlargement of the gland and thickening of the perirenal fascia.⁹ If neoplasms of the liver, pancreas, lymph nodes, or ovaries are present, the tumor masses may be noted.

The distribution and progression of ascitic fluid can be easily visualized with CT. In early ascites when the fluid is free moving and small in amount, it localizes in the cul-de-sac or pericolic gutters or the subhepatic space. Gravity causes the fluid to collect in the pelvis or the right subhepatic space. Negative pressure beneath the diaphragm "pulls" fluid beneath the diaphragm (Fig. 42-14). Fluid can loculate in unusual locations when the distribution is altered by adhesions or fibrinous material. When ascitic fluid becomes massive, it distends the peritoneal spaces.

Some authors have attempted to characterize the density of ascitic fluid in the disease processes,^{14, 16, 40} but this has not been consistent. Some specialists have asserted that purulent ascites has a higher density than transudative fluid. Although it is true that the higher the protein content of the fluid, the higher the attenuation number, I have not found the high density specific enough to be uniformly helpful except in the presence of intraperitoneal bleeding. One important diagnostic point about detecting small amounts of fluid should be made. Intravenous (IV) contrast material is helpful because it permits opacification of normal structures, which enhance compared with fluid.

Rather than using the density as a critical factor, I have found the mobility of fluid and the presence of effacement more helpful (Fig. 42-15). If intraperitoneal fluid is localized to a single area, I place the patient in a decubitus position to see if the fluid moves. In a patient who is not immunosuppressed, infected fluid does not move, whereas sterile fluid usually shifts (see Fig. 42-15B). In an immunosuppressed patient, this has not been a useful sign.

Although the finding of focal displacement or effacement of organs may suggest infection, this sign has limitations with loculated ascites. Any active process, inflammatory, neoplastic, or other, can deposit fibrin at the margins

Figure 42-15. A, With the patient in the supine position, fluid (arrow) adjacent to the small bowel suggests an abscess. B, When the patient is scanned in the decubitus position, the fluid moves away, indicating that it was not loculated and was unlikely to be an abscess.

of a space and thereby produce a fluid collection under pressure, when there is active production of fluid. On the basis of the CT image alone, it is virtually impossible to distinguish loculated ascites, abscess, or loculated neoplastic fluid. The only way to clarify the diagnosis is to obtain fluid by percutaneous aspiration, to inspect it, and to inoculate it onto culture medium.

If the pyogenic peritonitis is produced by intestinal perforation or if there are gas-forming organisms, free gas can be seen within the peritoneum.^{44, 70, 104} In a rare but deadly type of peritonitis produced by gas-forming organisms such as *Clostridium*, the amount and distribution of gas may be so extensive and diffuse that it is difficult to determine the extraluminal nature. I misdiagnosed one case of clostridial peritonitis in a patient with an extensive sarcoma because I mistakenly thought the free "gas" around clumps of tumor was the gas in the bowel being compressed by a large mass.

Tuberculous and Granulomatous Peritonitis

Tuberculous peritonitis is said to occur in 3.5% of patients with pulmonary tuberculosis.^{35, 73} It is a rare disease that is a result of disseminated miliary tuberculosis of the bowel and peritoneum. It is thought to be a result of hematogenous spread or local spread from GI involvement (penetration of involved bowel or lymph nodes draining into the peritoneum).^{44, 45}

Classically, it is divided into a "wet" form with large exudates, and a "dry" form,^{73, 115, 120} which has large amounts of inflammation caused by fibrinous exudates and tubercles.

There have been several reports about tuberculous peritonitis. Soft tissue densities produce thickening of the mesentery, omentum, and bowel wall. The lymph nodes in the mesentery and retroperitoneum may be increased in number and size (Fig. 42-16). The findings are not specific, and this entity cannot be diagnosed without a high index of clinical suspicion. On occasion, histoplasmosis may involve the abdomen and produce lymph node enlargement in the abdomen (Fig. 42-17).

Figure 42-16. CT scan of a patient with intra-abdominal tuberculosis. There is fluid in the pericolic spaces (p) and large lymph nodes (arrows) in the retroperitoneum and mesentery.

Figure 42-17. CT scan shows enlarged lymph nodes beside the aorta and behind the vena cava (V), resulting from histoplasmosis.

Hemorrhage

With hemorrhage into the peritoneum, the blood can be visualized quite easily (Fig. 42-18). When the earliest signs of hemorrhage are sought, the organ and the adjacent peritoneal spaces should be looked at quite carefully. The right subhepatic space, pericolic spaces, pelvis, and renal fascia should be examined (Figs. 42-19 to 42-21). When splenic injury is suspected, the most posterior portion of the pericolic space or the anterior renal fascia should be examined. Because the posterior of the space is dependent, blood accumulates there. The renal fascia may become thick if bleeding into the bare area behind the spleen occurs.

In contrast to other areas of the body where the breakdown of blood changes density over a period of days or weeks, density changes are much more rapid within the

Figure 42-18. Large collection of blood in the anterior peritoneum. CT scan shows a large fluid collection containing internal clot. Arrows define the posterior wall.

Figure 42-19. High-density hematoma (H) outlines the margin of the liver (*arrows*). Because the peritoneum has significant fibrinolytic activities, the presence of intact hematoma usually indicates acute bleeding.

peritoneum. Because of the fibrinolytic activity of the peritoneum and rapid influx of fluid, the density changes occur quickly, over a matter of hours. Such lysed blood shows a low density, similar to any other fluid. When the hemor-

Figure 42-20. A hematoma in the right subphrenic space shows separation in the low-density serum component anteriorly, from the high-density blood products (*curved arrow*) posteriorly. The posterior margin (*vertical arrow*) of the subphrenic space is noted adjacent to the bare area (*horizontal arrow*) of the liver.

Figure 42-21. Extraperitoneal hematoma (H) contains serum and blood products. It is displacing the bladder (*arrow*) to the left.

rhage is recent or the bleeding is rapid, the peritoneum does not have sufficient time to lyse the clots, and blood appears as a high-density collection in the peritoneum or adjacent to the injured organ.

If a high-density “blood clot” is seen, it does not mean that the bleeding is stabilized but that the bleeding has been recent or rapid. Careful observation or intervention is needed (Fig. 42-22).

In cases of massive **extraperitoneal** bleeding, there may initially be some difficulty in defining the extraperitoneal location of the blood. With careful inspection, one can usually define the proper location by noting that the peritoneum is displaced inwardly. In the pelvis, the anterior extraperitoneal space indents the peritoneum posteriorly and may extend caudally below the cul-de-sac and above the bladder and rectum.

Hematomas in the abdomen go through the same evolution in density as other body areas. In early stages, a hematoma shows a homogeneous soft tissue density and then this changes to a mixed appearance of high density clot and serous fluid. Next, it usually evolves to a fluid density and then lessens in size until it is resorbed. In some unusual cases, the hematoma may simply shrink as a soft tissue mass.

Abscesses

Intra-abdominal abscesses are uniformly fatal if untreated and usually curable if properly treated.⁵ CT has proved useful in the detection and treatment of this entity.

Clinical Presentation

An abscess is an isolated collection of purulent material and is the **result of an unsuccessful attempt** by the body to eradicate organisms from a focus of infection. Before an abscess develops, the inoculation of a bacterium or yeast occurs and the body responds with antibodies and leuko-

Figure 42-22. Post-traumatic subphrenic blood in evolution. *A*, CT scan shows hematoma (arrow) around the margin of the spleen, resulting from traumatic injury. The high-density material indicates that the spleen was unstable, and an angiographic embolization was performed to prevent catastrophic bleeding. *B*, After the embolization of the spleen, the fluid collection contains high-density clot and air (arrow). The patient stabilized. *C*, A later scan shows spontaneous reduction in the amount of fluid and air around the spleen.

cytes to eliminate the infection. At this stage, there is a focal inflammation, phlegmon, or cellulitis. If the body defenses prevail, the cellulitis clears,^{38, 39, 102} if the organisms prevail and the focus of infection continues, a collection of purulent material results. With CT, it is usually not possible to detect an infection before it forms a fluid collection; in some cases, however, the process can be observed in evolution.

Normal Immune System

Patients with a normal immune system and an abscess have a typical clinical presentation. They have fever, tachycardia, leukocytosis, and symptoms localized to the area of the abscess. The localization of symptoms depends on the site of the abscess. Pain from the visceral peritoneum is carried by the splanchnic nerves and is poorly localized. When the parietal peritoneum is involved, the pain is more precisely localized. In such patients, the typical appearance of an abscess, which consists of well-defined fluid collec-

tions producing effacement of any adjacent anatomy, can be seen.

Immunocompromised Patients

Immunocompromised patients are a unique group that should be considered separately because of the lack of clinical signs and symptoms that may occur as a result of the altered immune system. Such patients may not exhibit fever or leukocytosis or discomfort by clinical examination.

Immunosuppression can be caused by a large number of factors, including corticosteroid medication, immunosuppressive agents, acquired immunodeficiency syndrome (AIDS), chemotherapy, or radiotherapy; patients with chronic diseases, such as hepatic cirrhosis, chronic renal failure, or malnutrition, may be immunocompromised. Some immunocompetent patients with abscesses initially appear to be handling an infection well, but after a short time they may unexpectedly decompensate. Fry and colleagues²¹ found clinical signs in only 7% of 143 immunocompromised patients.

CT is important because it can detect subtle abscesses, even if immunocompromised patients lack localizing symptoms. In some such cases, a fluid collection may have findings typical of an abscess; in other patients, little fluid may be seen and may not produce the typical pressure effacement. The fluid in an immunocompromised patient may not loculate, but it may be widely disseminated throughout all of the peritoneal spaces. In such cases, the only practical way to assess the significance of the fluid collection is to sample it by needle aspiration.

A good example of this dynamic process is the evolution of an infection in the kidney or liver. An early focal infection of the kidney produces focal interstitial nephritis, which has the appearance of a soft tissue mass. It may further evolve into an area of necrosis and finally a fluid collection, producing an abscess. In very early abscess, there may be only subtle density change without clearly defined liquefaction (Fig. 42-23).

An understanding of this evolution is especially important because of the widespread use of CT in detecting abscess drainage. If an infection is in the stage of inflammation that has no fluid to be drained, surgical or percutaneous drainage is not indicated. Attempts to drain such phlegmons fail and may lead to complications, such as hemorrhage.³⁰ Occasionally such abscesses may be treated effectively with antibiotic medications and require no drainage.

Imaging Appearance

The CT appearance of an abscess is quite characteristic. An abscess appears as an area of fluid density with well-defined or irregular margins, and it may contain multiple septations in the cavity (Figs. 42-23 and 42-24). Depending on the amount of debris, blood, or proteinaceous material, the attenuation value of that material may be the same as that of water or somewhat higher. Abscesses may contain gas, which appears in the CT scan as black densities. Gas may be abundant and produce an air-fluid level, or it may be scattered throughout the fluid-density area as small microbubbles. Approximately one third of abscesses contain gas (Fig. 42-25), which may be the result of a GI fistula or gas-forming organisms (most commonly, *Escherichia coli*, *Enterobacter aerogenes*, and *Klebsiella* and *Clostridium*). In some cases, there may be no well-defined fluid collections, or small pockets of gas may be the only sign of infection.

The most common example of gas as the only sign of infection is the presence of small gas bubbles around an infected aortic graft or emphysematous pyelonephritis. One diagnostic caveat is that of extremely small gas bubbles that may not measure -1000 Hounsfield units (HU) because of the partial-volume effect; such bubbles may measure only -200 to -300 HU. The nature of such gas bubbles, however, can easily be confirmed by adjusting the window center until the adjacent fat appears gray. Any structure darker than the gray fat represents gas.

CT and MRI are capable only of detecting a fluid or gas density but cannot determine whether such densities represent infection. For example, low-density fluid masses can be produced not only by abscesses but also by old

Figure 42-23. Large abscess (arrow) in the left lobe of the liver shows subtly decreased density, which represents a poorly liquefied inflammatory site. Administration of IV contrast material is critical to visualize such areas.

hematomas, lobulated ascites, lymphoceles, necrotic tumors, mucinous tumors, and benign cysts. Thus, aspiration may be necessary for diagnosis in these cases (see "Imaged Guided Microsurgery" chapter).

Although free air within the peritoneum may be due to abscesses, it also may be secondary to surgery or to a perforated bowel. In fact, parenchymal gas can occur after any surgical or percutaneous procedure, such as emboliza-

Figure 42-24. Large abscess (arrow) in the right lobe is significantly liquefied, showing a much better defined fluid collection, characteristic of an abscess.

Figure 42-25. Abscess cavity in a hepatic abscess shows air collections (*arrows*). Gas is typically present from gas-forming organisms, but it may also originate from fistulas.

tion that introduces minute amounts of air by tissue necrosis (see Fig. 42-22B and C).^{67, 70} The gas appears on the scan, but there may be the spurious diagnosis of infection. A large number of free, small gas bubbles may be the result of a perforated ulcer without any drainable purulent material. Careful scrutiny can distinguish small amounts of gas in bowel, which may be confusing (Figs. 42-26 and 42-27).

The fluid densities of virtually all abscesses are identical in appearance, whether the causative organism is a bacterium, yeast, or a parasite. The only exception is when tuberculosis or echinococcosis may occasionally be associated with calcification.

Figure 42-26. Small air collections in the bowel can be distinguished from abscess air by noting that the small pockets of air (*arrows*) are trapped in the margins of the small bowel valvulae. Free air (*curved arrow*) is noted anteriorly, in front of the liver.

Figure 42-27. Another patient shows air beneath the diaphragm anteriorly. The collection on the right (*large arrow*) is free air, whereas the air on the left side is located in a loop of small bowel. Careful scrutiny shows the small indentations from the bowel markings (*small arrows*), indicating this is intraluminal.

Technical Factors

When one is evaluating for an intra-abdominal abscess, two technical factors should be remembered. First, it is important to administer IV urographic contrast material in all instances (Fig. 42-28; see Figs. 42-23 and 42-25). Second, oral contrast material in either an iodinated or a barium solution should always be administered for opacification of the bowel. This is especially important for the

Figure 42-28. CT scan shows how beneficial IV contrast material is for a correct diagnosis. The fluid-density chump of bowel (*arrow*), representing an internal hernia, can be correctly identified because the contrast material enhances the bowel wall and valvulae. Without contrast material, it would exhibit a fluid density indistinguishable from that of an abscess.

evaluation of abscesses in the left subdiaphragmatic space, the omental bursa, or the interloop region.

Abscesses in each of the organ systems and anatomic areas have some unique clinical characteristics and appearances on CT images. In addition, each of the anatomic areas has some potential false-positive findings associated with the variants of normal and other abnormalities, which should be sought to avoid an incorrect diagnosis of intra-abdominal abscesses.

Right Subdiaphragmatic Abscesses

Abscesses in the right subdiaphragmatic space are caused by a variety of disorders because this area has open access from the right pericolic gutter and right subhepatic recess. Virtually any inflammatory process in the abdomen can reach this area. The most common cause of an abscess, however, is appendicitis or a perforated viscus, gallbladder, or ulcer. The whole abscess may show fluid density, or it may contain gas (Fig. 42-29).

The most important diagnostic point is that the peritoneal space ends at the coronary ligaments immediately lateral to the bare area of the liver. A pleural effusion should not be mistaken for a subdiaphragmatic abscess (see Fig. 42-14). If the fluid of abscess is behind the fat that is posterior to the bare area of the liver, it represents a pleural effusion and not a subdiaphragmatic abscess. Any fluid or gas within the fat of this bare area is in the superiormost portion of the pararenal space. If both a pleural effusion and a subdiaphragmatic abscess exist, a decubitus view may permit the pleural fluid to move and confirm the diagnosis. In some unusual cases, a bolus injection of contrast material with dynamic scanning may have to be used to visualize the diaphragm, which enhances because of its rich blood supply. Any fluid in the subdiaphragmatic space can resemble an abscess, whether it be bile, blood, necrotic tumor, or loculated ascites.

Figure 42-29. Subphrenic abscess containing fluid and air. The posterior margin (arrow) of the space borders the bare area of the liver.

Figure 42-30. CT scan shows free air (F) in the anterior subhepatic space adjacent to the gallbladder fossa. The posterior right subhepatic space (S) lies so high that it gives the erroneous impression of a hepatic fluid collection.

Right Subhepatic or Hepatorenal Abscesses

The right subhepatic space is located between the right lobe of the liver and the anterior surface of the kidney. It has been divided into anterior and posterior (Morison's pouch) compartments, a functional division based on etiologic conditions (Figs. 42-30 and 42-31). The most common cause of abscesses in the anterior portion is a perforated gallbladder that borders immediately on this area. The posterior portion of the space is a dependent area within the peritoneum that can collect fluid from the paracolic

Figure 42-31. Abscess in the posterior subhepatic space (Morison's pouch) between the liver and kidney. On occasion, as here, the curved surfaces create a partial volume effect, which may make it difficult to distinguish the abscess from a renal or perirenal fluid collection.

gutters, the subphrenic space, or direct extension from the duodenum, liver, or bowel.

Because this is such a common site for fluid collection, even with ascites, a distinction may have to be made between ascites and purulent material. In such cases, it is best to place the patient in a decubitus position to let the fluid move out of the space. Ascites moves, whereas inflammatory collections (in the immunocompetent patient) do not; this is a good differential point to mark the need for aspiration in some patients.

Another uncommon problem is that sometimes the cephalic extent of this space is high. When an axial scan is taken above the typical location of the space in such cases, it may give the spurious impression of an intrahepatic abscess.

Left Subdiaphragmatic Abscesses

An abscess in the left subdiaphragmatic space can be caused by a number of abnormalities. It has traditionally been said that access to this anatomic area is limited from other peritoneal spaces because of the phrenicocolic and falciform ligaments. The typical origin is the stomach or colon, secondary to a gastric ulcer; postoperative leaks; or a perforated neoplasm, left colon, or esophagus. In some cases of a perforated esophagus, the inflammatory process involves the retroperitoneal space rather than the subdiaphragmatic space; if a portion of the stomach is involved, however, the subdiaphragmatic space is also involved.

Most abscesses can involve the entire diaphragmatic space, but they also may loculate in an anterior or posterior segment (Figs. 42-32, 42-33, and 42-34). Although it is traditionally taught that a process cannot extend from the left pericolic space or the right subphrenic space, experience has shown that, depending on individual anatomic-

variations or the nature of the inflammatory process, the falciform ligament and phrenicocolic ligaments may not serve as effective barriers to the spread of infection (see Figs. 42-5A and 42-6A).

To detect a small abscess in the left subdiaphragmatic space, one must always administer oral contrast material to fill the stomach. At times, a fluid-filled stomach may resemble an abscess, or vice versa. The contrast material clearly defines the stomach and eliminates any question of the diagnosis.

Left-sided pleural effusion should not be mistaken for a left subdiaphragmatic abscess. The region between the upper pole of the left kidney and the spleen, which contains the splenic pedicle and tail of the pancreas, represents the splenorenal ligament. This region located behind the fat is within the pleural space and not the subdiaphragmatic peritoneal space.³³ Any fluid within this area is in the superiormost area of the retroperitoneum rather than in the left subdiaphragmatic space. Above the level of the splenorenal ligament, fluid can surround the spleen entirely and may become interposed between the diaphragm and the spleen (see pararenal space abscesses later). Any problems distinguishing pleural effusions from subphrenic collections can be overcome by putting the patient in the decubitus position.

It is often difficult to differentiate a subphrenic abscess from inversion of the diaphragm by a large pleural effusion. In the latter case, a large pleural effusion is seen adjacent to the diaphragm.

On first glance, it is difficult to distinguish a pleural effusion from a subphrenic collection, but if one looks carefully, the fluid is behind the spleen and the bare area of the spleen. A decubitus view or sagittal reconstruction may clarify the nature of the inversion.

Left Subhepatic Abscesses

Abscesses in the left subhepatic space are caused by the same processes as those causing the subphrenic abscesses. They may spread from the right side, beneath the falciform ligament, or from other portions of the left subphrenic space (see Fig. 42-34).

Omental Bursa Abscesses

Abscesses in the omental bursa may be secondary to a process extending through Winslow's foramen, inflammation from the pancreas, a penetrating ulcer, or a tumor from the stomach or duodenum. The inferior recess of the omental bursa is anterior to the pancreas and is most commonly involved through penetrating ulcers or a pancreatic process. A small amount of air may be the only sign of a perforated ulcer. As was noted previously, the splenic recess of the omental bursa is located directly behind the fundus of the stomach (Figs. 42-35 and 42-36). The medial superior recess extends cephalad adjacent to the caudate lobe and vena cava (see Figs. 42-37 and 42-38).

It is important to administer oral contrast material to see the posterior wall of the stomach and to distinguish it from an abscess in the splenic recess of the omental bursa

Figure 42-32. Three abscesses in different areas of the left subphrenic space. The most anterior portion of the space (*curved arrow*) is in front of the liver. An abscess is in the gastrohepatic space (*vertical arrow*), sometimes known as the left subhepatic space. The posterior subphrenic space (*horizontal arrow*) is around the spleen.

Figure 42-33. Left subphrenic abscess extension. *A*, Left subphrenic space around the spleen has variable appearance depending on the level. An abscess (*A*) in the most superior portion of the space over the spleen is against the diaphragm and displaces the spleen caudally. *B*, At this level, the abscess fluid collection has extended along the medial and lateral portion of the spleen (*S*). *C*, At the midportion of the spleen, the posterior margin of the space is limited (*arrow*) by the lienorenal ligament (bare area of spleen).

Figure 42-34. Abscess (*arrow*) in the left subhepatic (gastrohepatic) space behind the left lobe and adjacent to the stomach.

(Figs. 42-37 and 42-38). Air may remain in the omental bursa for several days after a surgical procedure and should not be mistaken for an abscess.

Pericolic and Interloop Abscesses

Pericolic abscesses can occur as a result of virtually any inflammatory process within the abdomen, such as a perforated colon or bowel, appendicitis, or a ruptured gallbladder because the physiologic movement of fluid is into the pericolic space (see earlier discussions of peritoneal function). Such abscesses are usually associated with a subhepatic or subdiaphragmatic abscess. On CT scans, a pericolic abscess appears as a mass of fluid density bordered on the lateral surface by the parietal peritoneum and medially by the serosa of the colon (Fig. 42-39). Such abscesses may spread into the right subhepatic or subdiaphragmatic space.

Interloop abscesses can be caused by the same conditions as any abscess but are more commonly associated with fistulas from the bowel. They can occur between

Figure 42-35. Abscess in a small child lying in the right decubitus position. CT scan shows a large abscess (A) in the space behind the stomach (S), anterior to the pancreas (P) and medial to the splenic flexure of the colon (C).

isolated loops of bowel or within the infracolic spaces. In such cases, it is best to give ample amounts of contrast material to try to opacify the bowel, but many times there is sufficient contrast enhancement of the bowel wall and the contents (see Fig. 42-28) to distinguish the abscesses.

When an abscess is present, bowel adjacent to the in-

Figure 42-36. Abscess in a patient lying in the supine position. CT scan shows a large abscess (arrow) in the splenic recess of the lesser sac, which is effacing the stomach anteriorly.

Figure 42-37. CT scan shows a small collection of contrast medium and air in the lesser sac (arrow) from a small gastric perforation.

flammation may be paralytic and may not carry the contrast. In such cases, a fluid-filled or gas-filled abscess can be distinguished from the normal bowel because the wall of the abscess is smooth and lacks the irregular contour of the bowel wall produced by typical haustra or valvulae. Moreover, the fluid in the bowel has a varied appearance with different densities, whereas an abscess is completely homogeneous.

Pelvic Abscesses

The pelvis, the lowest point in the abdomen and the area to which exudates gravitate, is one of the most com-

Figure 42-38. Fluid collection (arrow) in the superior recess of the lesser sac, around the caudate lobe (C) of the liver. (See Figs. 42-4, 42-5, and 42-6.)

Figure 42-39. Pericolic abscesses (arrows) on the right and left sides of the peritoneum.

mon locations for intra-abdominal abscesses. Abscesses in this area may result from diverticulitis, appendicitis, a perforated viscus, peritonitis, or trauma (Fig. 42-40A and B).

On CT scans, the abscess has a typical appearance, being low in density and well marginated; it may or may not contain gas. It is important to administer both IV and urographic contrast material to opacify the rectum and colon. Administration of both contrast materials should eliminate any false-positive results, especially in patients with ascites; the ascitic fluid in the pelvis may produce an area of fluid density on the image, which may be confusing.

Posterior Pararenal Space Abscesses

The posterior pararenal space is bounded posteriorly by the transverse fascia and anteriorly by the posterior renal fascia (Fig. 42-41A). This space extends caudad to the pelvis and cephalad to the diaphragm (see Fig. 42-41B). Although most clinicians are familiar with the posterior pararenal space in the area of the kidneys, the pararenal space in the area adjacent to the diaphragm is not as familiar. In the space between the medial portion of the spleen and the upper pole of the kidney is the splenorenal ligament, which represents the farthest extension of the pararenal space on the left side. There is an analogous space in the right side in the bare area of the liver. It has been my experience that both the anterior and posterior pararenal spaces communicate into these areas on the right and left sides, although this is not the traditional teaching.

Inflammatory processes in the posterior pararenal space usually result from a ruptured aortic aneurysm, pancreatitis, osteomyelitis from the rib or spine, intestinal or esophageal perforation, or trauma. Abscesses may remain localized laterally within the pararenal space or become confluent with the psoas muscles. Processes from the aorta or spine

may spread laterally. In addition to the abscess collection, there is concomitant thickening of the fascial planes. A psoas abscess produces enlargement of the psoas muscles.⁹¹ This abscess typically shows fluid density but occasionally the density may be similar to that of the muscle (Fig. 42-42). In cases of bilateral psoas abscesses associated with destruction of the vertebral body, tuberculosis should still be considered.

Although little information is available in the literature, several cases indicate that the posterior pararenal space communicates with the posterior mediastinum. Esophageal perforations or other problems may extend caudally into the right or left posterior pararenal spaces, or vice versa.

Anterior Pararenal Space Abscesses

The anterior pararenal space is bounded anteriorly by the posterior parietal peritoneum and posteriorly by the anterior renal fascia; this space is bounded laterally by the lateroconal fascia (which is the fused anterior and posterior perirenal fasciae). This compartment contains several alimentary organs, including the pancreas and ascending and descending colon. (This anatomic discussion is based on the traditional viewpoint; a new concept of the retroperitoneum proposes that there is no free communication between the space around the pancreas and the colon but that they are interconnected only through the attachment of the mesentery. In addition, the new concept no longer uses the term *anterior pararenal space* but considers these areas the *intermesenteric spaces*; see "New Concepts of Retroperitoneum and Peritoneum" earlier.)

Most inflammatory processes in this area originate from the colon, appendix, pancreas (see Fig. 42-41A), or duodenum as a result of perforations from tumors, diverticulitis, inflammatory bowel disease, or trauma. Perforations of the bowel can produce gas, abscesses, or both, depending on the site of involvement. A localized perforation of the colon may occur in the retroperitoneal area and remain confined to the anterior pararenal space. If the process occurs below Gerota's fascia, it can move superiorly into both the anterior and the posterior pararenal spaces. The most cephalic extension of the pararenal spaces on the right is the retroperitoneum behind the bare area of the liver, and on the left it is the retroperitoneum medial to the spleen.

Another sign I have found to be valuable in cases of inflammation is thickening of the renal fascia. For example, in some cases it may be difficult to distinguish a loop of bowel with the density of fluid from an abscess; with an abscess, the renal fascia is thickened.

Liver Abscesses

Pyogenic hepatic abscesses usually occur as a result of intra-abdominal infection, such as appendicitis, suppurative cholangitis, hematogenous dissemination by the portal vein draining the bowel, or hematogenous spreading from a distant focus.^{49, 86} The most common pyogenic organisms include gram-negative organisms, especially *E. coli*; less commonly, anaerobes, such as *Clostridium* or *Bacteroides*

Figure 42-40. Pelvic abscesses. *A*, Pelvic abscess (*horizontal arrow*) shows large abscess anterior to the rectum. This unusual abscess resolved with only antibiotic therapy. *B*, After almost complete resolution of the abscess (*arrow*), the patient did not require drainage. *C*, In a different patient, CT scan through the upper portion of the pelvis shows an abscess with an air-fluid level (*straight arrow*) next to a loop of sigmoid (*curved arrow*).

Figure 42-41. *A*, Retroperitoneal abscess in the pararenal spaces, anterior (AP) and posterior (PP). Fat (*arrow*) is seen within the renal fascia, bounded anteriorly by the fascia of Gerota and posteriorly by the Zuckerkandl fascia. Slightly thickened fascia (*curved arrow*) can also be noted on the left. *B*, The superior-most extent of this retroperitoneal abscess (*arrow*) continues in the bare area behind the liver.

Figure 42-42. A, CT scan of a child with vasculitis and local perforation of bowel. A retroperitoneal abscess is seen in the right iliopsoas muscle (arrow). B, Abscess extends caudad through the psoas muscle and over the area of the lesser trochanter (arrow).

species, also may be involved. Antibiotic therapy and drainage, either surgical or percutaneous, are indicated. The typical CT appearance of a hepatic abscess is a circumscribed mass with the density of fluid (Fig. 42-23). Amebic abscesses and echinococcosis are also types of hepatic abscesses (see next).

Two potential false-positive findings are commonly associated with the liver. The first is the partial-volume effect produced by the upper pole of the right kidney. The space between the two is not clearly visualized but appears lower in density as a soft tissue mass; this may simulate a perirenal collection on the right side. The key to differentiating this partial-volume error from a real perirenal collection is that there is ipsilateral thickening of perirenal fascia if an abscess is present.

The second potential false-positive finding is a high hepatic flexure of the colon entering the porta hepatis. The course of the transverse colon to the hepatic flexure of the colon should be carefully traced; at times, a decubitus view may be required to confirm the diagnosis.

Amebic Abscesses

Amebic abscesses are a complication of colonic infestation by *Entamoeba histolytica*. The disease is produced when material contaminated with amebae is ingested. Amebae reach the liver either by the portal drainage or by the lymphatic vessels from the bowel.⁴⁹ Once in the liver, the amebae release autolytic enzymes and inflammation progresses until an abscess is produced. Such abscesses can become secondarily infected by pyogenic organisms, which may or may not be gas producing. The treatment of amebic abscesses consists of antibiotic therapy or surgical drainage, or both. Total resolution of the amebic abscess can occur without complete drainage with proper medical therapy consisting of metronidazole. (The material aspirated from such amebic abscesses has the appearance of

anchovy pate and consists of autolyzed liver tissue.) Surgical drainage may be required in some abscesses that have become superinfected with pyogenic organisms. The CT scan appearance of an amebic abscess is identical to that of a pyogenic abscess.⁵⁸ It appears as well-delineated masses of fluid density within the liver substance (Fig. 42-43).

Fungal Infections

A number of different fungal infections can cause focal infections, *Candida* the most common. With most fungi, the early foci may show low density and be poorly defined, but they may liquefy into well-margined fluid collections (Fig. 42-44).

Echinococcosis

Echinococcosis, or hydatid disease of the liver, is a parasitic abscess caused by the larvae of *Echinococcus multilocularis* (alveolaris) or *E. granulosus*. The dog is the host, and sheep are the intermediate hosts; humans may become intermediate hosts by ingesting food contaminated by the ova. The pathophysiologic conditions follow: After ingestion of the ova, the embryo, which penetrates the intestinal wall and is transported to the liver by the portal system, is released. (Although echinococcosis can occur virtually anywhere in the body, the liver is the most common organ involved.) Once in the liver, the larva establishes itself, and inflammation proceeds. The hepatic cyst produced is composed of the endocysts, comprising the parasitic elements of the germinal membrane and daughter cysts, and the surrounding pericyst, which is the compressed hepatic parenchyma and inflammatory reaction.

Pathologically the two types of *Echinococcus* organisms differ. *E. granulosus* may have (1) a unilocular cavity,

Figure 42-43. A, A large amebic abscess (arrow), which looks similar to other abscesses. B, Resolution of the amebic abscess occurred over a number of months after administration of antibiotic medications.

which is usually fertile, or (2) a multilocular cavity with irregular edges, which does not metastasize. Calcifications may indicate sterility. *E. multilocularis* produces small, numerous cysts that multiply by exogenous budding to produce the malignant hydatid cyst, which can become confluent throughout the liver or metastasize to other organs.

Although the liver is the most common site of echinococcal involvement,⁵³ lung and kidney are not uncommon sites. Unusual reports of many other sites, including pancreas, aorta, and brain, have occurred.⁵²

Treatment of an echinococcal abscess has historically been possible only by surgical drainage,²² but medical drainage methods have improved. Several chemical agents have been effective. For example, mebendazole has proved effective in a large percentage of patients,¹⁰⁹ with cure in 40%. Changes are produced in cyst appearance, such as a totally echogenic appearance on ultrasound, increased density of cysts, reduction of cyst size, detachment of endocysts from the wall, and calcification of the cyst wall.

Percutaneous drainage can be performed if a “killing” solution (10% povidone-iodine [Betadine], 20% sodium chloride, or ethyl alcohol) is injected and meticulous technique is used to prevent spillage, but it should not be

performed unless significant symptoms or complications exist. Surgical drainage consists of complete removal of the intact cyst after the killing solution has been injected into the cyst. (Formalin has been abandoned because of adverse effects.) The greater omentum is usually sutured over the remaining cavity in the liver to preclude any spillage of residual fluid or cysts into the peritoneal cavity.

In recent years, percutaneous treatment and drainage have become common, with several techniques reported.⁸⁹ These are discussed in Chapter 61. Lewall and Nyak⁶³ have cautioned that percutaneous drainage should be avoided and surgical drainage encouraged when echinococcal cysts show dilatation of the biliary system or an exophytic component that is likely to rupture.

The CT follow-up of such cases is informative because of the clear visualization of the anatomy. Before surgical treatment, the large mother cysts containing the daughter cysts are clearly seen (Fig. 42-45). With some of the new chemotherapeutic agents available, temporary improvement in the cysts can occasionally be seen, as evidenced by some dissolution of the walls of the daughter cysts. Whether such medical treatment will be effective in the long term is not known.

After surgery, the residual cavity can be clearly distinguished from the evacuated cyst and the fat density of the omentum, which is used to seal the cavity (see Fig. 42-45D). For several weeks, the size of the cavity shrinks and the amount of fat seen decreases as the fibrosis of healing continues.

In some cases, there may be secondary infection of daughter cysts by colonization from a biliary fistula. In such cases, air may be seen within the cysts from either pyogenic bacteria or a biliary fistula, which usually accompanies the infection. On some occasions, the pyogenic organisms can actually destroy the daughter cysts by enzymatic digestion (see Fig. 42-45B, C). Diagnostic aspiration should be avoided because of potential spillage of the daughter cysts and anaphylaxis from the foreign protein. Sensitization of the patient to the protein is necessary for anaphylaxis to occur; this usually follows a previous spillage of material, although it may occur without such an event.

Complications associated with the disease include rup-

Figure 42-44. Fungal granulomas appear as small, low-density masses (arrowheads) in the right and left lobes of the liver.

Figure 42–45. Echinococcal cyst evolution with treatment. A, CT scan of echinococcal cyst shows calcification in the wall (curved arrow) and daughter cysts (arrow) within the mother cyst. B, After secondary infection, air can be seen within a cyst. This scan shows multiple air pockets within the cyst and air within the biliary system (curved arrow). C, With persistent infection, dissolution of the daughter cysts can be seen. Note the air (arrow) in the upper portion of the cyst and the absence of daughter cysts. D, After surgery, the cavity, filled with fat-density omentum (arrow), can be seen.

ture of the mother cyst and spillage into the peritoneum or adjacent structures. In approximately 10% of cases, secondary infection may occur because of erosion into the bowel or the biliary system.

Since the early reports of the CT appearance of echinococcosis,⁸³ numerous articles discussing the CT detection and appearance of echinococcal cysts of the liver have appeared.^{52, 53, 63, 110} Scherer and colleagues⁹⁹ reported on the CT evaluation of 13 cases of echinococcosis and noted two distinct appearances. In six of eight cases involving *E. granulosus*, the cysts appeared as masses of fluid density (3 to 30 HU) with a radiodense rim. In six of eight cases, there was calcification, and in five of those six, the calcifications were either crescent or ring shaped. Daughter cysts were visible in the larger cyst in six cases.

In five patients infected by *E. multilocularis*, the lesions were seen as low-density masses (14 to 38 HU), without a well-defined membrane. In four of five cases, small nodular calcifications were present (never ring-shaped). Gonzalez and coworkers²⁸ reported on the accuracy of detecting hepatic echinococcosis with CT. They reported that CT diagnosis was correct in 19 of 19 cases. They noted that CT was the preferred modality because it “clearly and precisely shows the existence, number, size, and location of cysts and also yields data allowing assumption as to their vitality.”

Splenic Abscesses and Splenitis

Splenic involvement directly or indirectly by infection is quite common. In addition to abscesses, a wide spectrum of inflammatory changes can occur with pyogenic or granulomatous disease.

Pyogenic systemic infections can cause diffuse acute splenitis or focal fluid-density abscesses. Pathologically, small septic infarcts with systemic sepsis, which have been called “milk-flecked,” may be seen. These small collections may be below the level of resolution of the CT scanner, so they can be missed. With larger amounts of inflammation and infection, the typical intrasplenic abscesses, which are associated with endocarditis, AIDS, or IV drug abuse, can be seen (Fig. 42–46). Granulomatous processes, such as tuberculosis and histoplasmosis, are quite easily seen as clearly delineated calcium deposits. From gross pathology, it is known that granulomatous processes are associated with infarcts. There is limited information available on this point, but I have noted the association of infarct-like areas in the spleen with such patients (Fig. 42–47).

Nonspecific splenomegaly without splenitis can occur with a variety of systemic disorders, including parasitic infestations, systemic sepsis, and AIDS-related disease. In many cases of patients with myeloproliferative disorders,

Figure 42-46. Splenic abscess (A) is totally replacing the spleen.

Figure 42-47. Tuberculosis. A, CT scan shows a low-density area (arrow) in the spleen, believed to be early changes of tuberculosis. B, A follow-up scan shows resolution of the area several months after the institution of antituberculous therapy.

such splenomegaly may be associated with the underlying disease or borderline infection.

Renal Abscesses

Renal abscesses may be caused by hematogenous “seed-ing,” in which the organism is usually *Staphylococcus*, or a urinary tract infection, in which the organism is usually *E. coli*, *Proteus mirabilis*, or *Enterobacter aerogenes*. An intrarenal abscess is low in density and well margined and may resemble a renal cyst (Fig. 42-48). More commonly, an abscess has a more irregular margin and higher density and produces unilateral thickening of the renal fascia, whereas cysts seldom do this. When the infection is still an inflammatory phlegmon and not a fluid collection, there may be a focal area of enlargement that is isodense with a normal enhanced kidney but low in density with IV contrast enhancement. This area of localized inflammation and focal enlargement is the focal nephritis, or nephronia.⁹⁶ If the infection resolves, the kidney may return to normal; if it progresses, an abscess may form (Fig. 42-49).

Emphysematous pyelonephritis is an uncommon disease produced by gas-forming organisms and usually occurs in patients with diabetes (Fig. 42-50). On CT scans, the kidney may show small gas densities within the parenchyma, or may appear as a gas-filled structure barely recognizable as a kidney. A spurious finding of “gas” can be produced by embolization or infarction.¹¹⁶

An earlier form of the disease in the infectious spectrum shows even more subtle, temporary changes in the kidney. With diffuse pyelonephritis, a striated appearance, or focal areas of decreased enhancement, can be seen. These areas usually resolve with adequate therapy.

Polycystic renal disease associated with an abscess is a difficult clinical problem. By looking at the CT image, one cannot distinguish an infected cyst from the multitude of other cysts within the kidney. In such cases, a gallium scan is helpful in finding an infected cyst among the other cysts of fluid density.

Perirenal Space Abscesses

Abscesses of the perirenal space, confined by the renal fascia, are usually caused by spread of renal infection. The most common infecting organisms are *E. coli*, *E. aerogenes*, and *P. mirabilis*.

The cross-sectional CT findings of a perirenal abscess are an area of fluid density surrounding the kidneys, bounded by the renal fascia (Figs. 42-49 and 42-50). In all cases, there is concomitant thickening of the renal fascia (Fig. 42-51). The partial-volume effect associated with the right kidney and medial margin of the liver should not be mistaken for a perirenal collection.

Other Considerations

One of the greatest advantages of CT is its ability to image all areas completely. This accurate localization is especially important for the preoperative evaluation of ab-

Figure 42-48. Abscess. The importance of administering IV contrast material. *A*, Before administration of contrast material, the CT scan shows no visible abnormality. *B*, After administration of intravenous contrast material, the CT scan shows enhancement of the renal parenchyma, but the abscess exhibits very low density and a clearly defined margin (*arrow*).

scesses to facilitate their drainage. With CT, it is possible to determine the full extent of an inflammatory process and to detect multiple concurrent abscesses. This latter point is especially important because one must always be concerned about the occurrence of multiple, concurrent abscesses. This information is especially important in regard to patients who are to undergo surgical procedures, but it is absolutely critical if percutaneous drainage is considered.^{24, 29-32} For accurate localization of abscesses before percutaneous drainage procedures, the consensus in the

literature is that CT is superior to other imaging systems and is the modality of choice.⁵⁹ Given equal availability of the instrumentation, CT should be used as the initial diagnostic modality when percutaneous aspiration drainage of an intra-abdominal abscess is anticipated.

Finally, another important advantage of CT is its ability to determine the initiating cause of abscesses. Entities such as appendicitis, diverticulitis, cholecystitis, and penetrating ulcers can sometimes be suspected or recognized. With appendicitis, the diagnosis is suggested by a fluid collection

Figure 42-49. Progression of multifocal bacterial nephritis to a frank abscess. *A*, Post-contrast-enhanced image of the kidney demonstrates the typical defects of multifocal bacterial nephritis (*arrows*). Pre-contrast-enhanced images were normal. *B*, Post-contrast-enhanced image 1 week later demonstrates more severe changes of bacterial nephritis and liquefaction (*arrow*), with extension beyond the renal capsule. Surgery revealed an abscess in a “dead” kidney.

Figure 42-50. Emphysematous pyelonephritis. A, CT scan showing fistula (arrowhead) from the colon into the left kidney. Note the abscess extension (curved arrow) into the posterior pararenal space. B, This lower scan shows air within the left kidney and the air-fluid level in the pararenal space (arrow).

adjacent to the cecum or edema in the retroperitoneal fascia. With diverticulitis, the air-filled diverticuli adjacent to the abscess, which is of fluid density, can be recognized. Penetrating ulcers cannot be seen, but because of gas adjacent to the duodenum or in the omental bursa, the diagnosis should be suspected. In other cases, CT may not provide enough information, and other radiologic procedures or investigations are needed.

Mycotic Aneurysms

Mycotic aneurysms of native vessels are a rare event. It is believed that such infection must be superimposed on a diseased vessel and that it occurs as a result of hematogenous or direct spread. In cases of non-gas-forming organisms, there may only be a fluid collection in direct proximity to the vessel. In patients with a gas-forming infection, small bubbles of gas can be seen.

Infected Synthetic Grafts

Infection of synthetic grafts is a disastrous complication of vascular reconstructive surgery. The incidence of graft

infections is as high as 6%, and they are associated with a high rate of morbidity and mortality. The potential causes of the infection are contamination, small GI fistulas, or hematogenous seeding. Gram-positive organisms that can cause infection of grafts include *Staphylococcus epidermidis*, other *Staphylococcus* species, and *Streptococcus faecalis*. The gram-negative organisms commonly encountered in such graft infections include *E. coli* (the most common) and *Klebsiella*, *Enterobacter*, *Proteus*, *Pseudomonas*, and *Bacteroides*. Before CT, the diagnosis of graft infection depended on such standard radiographic techniques as GI studies or angiography. By the time such studies revealed the infection, however, the patient was often beyond the point of cure, even with proper surgical therapy. With CT, it is now possible to detect accurately fluid and gas collections that may indicate infection in and around synthetic grafts (Fig. 42-52).

The typical findings of infected aortic grafts depend on the type of organism involved. Gram-positive cocci that do not produce gas produce a fluid collection in the aneurysm bed or adjacent to the graft itself (Fig. 42-53A and B). When the infecting organism is gas forming, such as *E. coli*, or there is a small enteric fistula (Fig. 42-54), there are small microbubbles of gas in and around the graft. Several possible causes of false-positive findings exist in such cases. If a significant amount of blood or old hematoma is around the graft in the aneurysm, it too appears to be an area of fluid density. Normal postoperative gas may also be present within the aneurysm bed adjacent to the graft 7 to 10 days after surgery.⁹⁴

Because of the high mortality rate associated with this disease, radiologists have now adopted an aggressive approach for confirming the presence or absence of infection. In any case of a possible infected aortic graft, we now think that a CT-guided aspiration through the retroperitoneum is imperative to obtain a culture of the material around the aneurysm directly and determine whether infection is present (see Fig. 42-53B and C). This is important because in infected patients, expeditious surgical treatment consisting of removal of the graft and an axillofemoral bypass is typically performed. When aspiration results are normal, an extensive, complicated, and difficult surgical procedure

Figure 42-51. Perinephric abscess (arrow), contiguous with the renal parenchyma.

Figure 42-52. CT scan shows a fluid collection (A) containing gas bubbles (arrows), adjacent to the area of the aortic bifurcation.

may be avoided. With the improved diagnostic accuracy of CT and the more potent antibiotics, some surgeons are now deferring surgery if the infectious area is not adjacent to the anatomic site. Advances with urokinase enhancement of percutaneous drainage may improve the outcome of percutaneous treatment in such cases.^{57, 88}

Accuracy in Relation to Other Modalities

Since the introduction of CT, several authors have discussed its usefulness for detecting abscesses. The first article by our group³¹ reported a correct diagnosis for 20 of 22 abscesses. Since this first report, numerous others (including Callen,¹⁵ Gerzof et al,²³ Aronberg et al,⁶ Korobkin et al,⁵⁶ Levitt et al,⁶² Wolverson et al,¹¹⁷ and Knochel et al,⁵⁵) have confirmed the high detection rate of CT for abscesses. Data are sparse, but some comparative information is available about other imaging systems, such as ultrasound and gallium 67 citrate. In our initial report, CT was correct for 20 of 22 abscesses, gallium was correct in six of nine abscesses, and ultrasound was correct in one of two abscesses. Korobkin and colleagues⁵⁶ reported CT correct in 9 of 9 abscesses, gallium in 9 of 12, and ultrasound in 12 of 12. Levitt and coworkers⁶² found CT to be correct in six of six abscesses and gallium correct in nine of nine.

More recently, Knochel and colleagues⁵⁵ presented larger numbers of cases with which to compare CT and

Figure 42-53. Suspected graft infection. A, CT scan of a patient in the decubitus position before needle procedure. There is a large amount of fluid and old blood in front of and behind the prosthetic graft (A). B, To separate cultures and prevent cross-contamination, separate aspirations from the anterior and posterior areas were taken. The needle is carefully guided between the colon (C) and kidney (K) to ensure sterility. The "double" appearance of the needle is the result of motion. C, A more posterior approach was taken for the aspiration of the posterior fluid collection. A trajectory was planned through the psoas muscle to prevent any possible contamination.

Figure 42-54. Infection caused by fistula. A, CT scan shows a small air collection (arrow) adjacent to the left iliac limb of a prosthetic graft. B, Communication with the colon is verified by leakage of contrast material (arrow) from the bowel to the graft.

ultrasound, but they did not include gallium isotope scanning. In their series, CT was the most accurate modality, with a sensitivity rate of 97.5% and a specificity rate of 95%, whereas ultrasound had a sensitivity rate of 82% and a specificity rate of 94.5%.

In the literature and at meetings, there is always a controversial debate about whether the use of CT is justified when ultrasound is also good and only 10% to 13% less accurate. Proponents of ultrasound argue that it is less expensive and does not use radiation. CT advocates point out that abscesses are curable, and therefore the 10% increased accuracy is worth the additional expense and radiation.

I have formulated an approach to these modalities on the basis of several principles. According to the guideline about medical decision making set by McNeil and colleagues,⁷⁶ any false-negative results must be minimized with a curable disease, and therefore significant costs and efforts to find and treat such a disease are justifiable. With this reasoning, I can rationalize using CT for all patients. Realistically, however, a CT device is a limited resource; thus one must maximize the diagnostic return and not overuse it improperly. I believe that CT, ultrasound, and gallium scanning are complementary, in that the patient can best be cared for by taking into account the advantages and disadvantages of each modality. An acutely ill patient does not have the luxury of waiting hours or even days for the results of an isotope test.⁷²

Therefore, I prefer using an immediate imaging system, such as CT or ultrasound. Considering the various anatomic areas within the abdomen and technical considerations of each modality, the best-suited method for each case can be selected. Thus, if the patient is acutely ill and has focal symptoms in the right upper quadrant, retroperitoneum, or pelvis, ultrasound should be the modality of choice. If the ultrasound results are normal in these areas and the patient is toxic, examination with CT is appropriate. If the patient has focal symptoms in the left upper quadrant, pancreatic area of midabdomen, CT is the preferred modality. If the patient is acutely ill or immunocompromised with general symptoms and no focal signs, CT is the modality of choice because it can evaluate all areas without difficulty.

Finally, if the acutely ill patient has drains, wounds, or

external appliances, CT is better suited immediately after surgery because it does not require a coupling agent to the skin. If the patient is chronically ill, a gallium scan should be performed to locate the potential area of infection. Depending on the region of uptake, one should use ultrasound (in the right upper quadrant, pelvis, and flank) or CT (in the left upper quadrant, pancreas, and abdomen).

Peritoneal and Mesenteric Abnormalities

Only a limited number of benign and malignant tumors affect the mesentery and peritoneum. The most common of these abnormalities are neoplastic diseases, but less commonly benign abnormalities of the mesentery can be seen.

Peritoneal Cysts

Peritoneal cysts are unusual cystic masses that may be attached to the mesentery or peritoneum. The origin of these abnormalities is poorly understood, but some believe they are related to lymphatic abnormalities that produce sequestered secondary cysts. They are typically lined with endothelium. The cysts may be unilocular or multilocular. Clinically, they produce the same symptoms as an abdominal mass; surgical treatment is curative.

On CT images, these cysts appear as large, low-density masses with clearly demarcated fibroconnective tissue walls (Fig. 42-55). No unique imaging features distinguish these cysts from other low-density masses, such as mucinous metastases, abscesses, or hematomas. In such cases, the clinical history is important, and if indicated, a percutaneous puncture for cytologic or bacteriologic study can be performed.

The differential diagnosis of peritoneal cysts includes lymphangioma, nonpancreatic pseudocysts, enteric cysts, duplication cysts, and cystic mesotheliomas. According to Ros and coworkers,⁹⁵ differentiation among these entities is not possible using current imaging techniques.

Figure 42-55. Mesenteric cyst. A, CT scan shows a mass (arrow) that proved to be a mesenteric cyst. B, CT-guided procedure proved the true nature of the mass. The trajectory chosen avoids any loops of bowel, thereby preventing the possibility of contamination.

Desmoid Fibromas

Desmoid fibromas are unencapsulated infiltrating fibromas occurring predominantly in women and in any part of the body, including the abdomen.⁶⁹ There is a high association of fibromas of the abdominal wall and peritoneum with familial polyposis syndrome,⁷⁵ and fibromas are one of the classic signs of Gardner's syndrome. In one series of 44 intra-abdominal desmoid fibromas, 41 occurred within the mesentery.⁷⁵ The main clinical problem that arises with such desmoid fibromas is distinguishing these tumors from neoplastic masses resulting from colonic carcinoma. Pathologically, the tumor is benign but difficult to distinguish from a low-grade fibrosarcoma; however, there have been no reported metastases. Occasionally, the lesion may cavitate and enlarge quickly by the imbibition of fluid. The treatment is surgical excision, but unless complete and meticulous resection is performed, recurrence is the rule.

On a CT scan, a desmoid fibroma appears as a mass of soft tissue density within the peritoneum, displacing other intra-abdominal organs (Fig. 42-56). No unique imaging traits distinguish these fibromas from neoplastic masses, such as lymphomas and metastatic disease, or even from

other benign masses, hematomas, or high-density peritoneal cysts (Fig. 42-57).

Retractile Mesenteritis

Retractile mesenteritis is an unusual disorder of the mesentery consisting of diffuse inflammatory thickening of the mesenteric fat.^{18, 54} The cause of the abnormality is unknown. Pathologically, there is fibrosis, inflammation, and fatty infiltration. *Retractile mesenteritis* is the term used when fibrosis predominates. The process originates in the root of the mesentery and then can extend diffusely throughout the mesenteric fat. The disease process is confined to the mesentery, and there are no abnormalities of the intestines or vessels.⁵⁴

On CT scans, the mesentery does not appear to be of normal fat density but appears as an area of soft tissue density (Fig. 42-58). The bowel is not in its normal anterior location but is retracted posteriorly. One group²⁶ reports calcifications in some unusual cases of retractile mesenteritis and some resolution of the mesenteritis after treatment with steroids. In unusual cases, narrowing and rigidity of

Figure 42-56. A, Desmoid fibroma (D) involving the pancreas, which simulates a neoplastic tumor. Infiltration into the biliary system and portal hepatitis is occurring and producing benign, aggressive extension with almost "malignant" properties. B, Lower scan taken through the pelvis shows an ill-defined mass behind the cecum and adjacent to the psoas.

Figure 42-57. A, A number of mesenchymal tumors have a soft tissue density appearance that is nonspecific. This scan shows a leiomyoma of small bowel (arrow), which is exophytic. B, Hemangiomatous mass in mesentery has well-defined margins with some calcification (arrow).

the colon with thumbprinting or displacement of bowel by mesenteric masses may be seen.¹⁰⁶ Han and coworkers³⁴ reported a case involving the colon that produced transmural thickening of the colon.

With extensive metastatic disease to the peritoneum and mesentery, findings may simulate retractile mesenteritis (Fig. 42-59). In such cases, tumor implants in the mesentery produce increased density and may also restrict movement of bowel as visualized with ascites.

Inflammatory Processes

A number of inflammatory processes associated with the bowel, peritoneum, and mesentery produce certain predictable changes on CT scan. The findings of edema, bowel wall thickening, fluid distention, and fibrosis are nonspecific.

Crohn's disease causes transmural inflammation of the bowel, which produces fairly typical findings. Characteristically, thickening of the bowel wall associated with soft tissue density, edema, and fibrous reaction is seen. On occasion, an increased amount of fat separating several loops of bowel is seen; it has been said that this represents proliferation of fat, but the cause of such fat accumulation is not known.

Ulcerative colitis produces only thickening of the bowel wall without producing changes within the mesentery. Dilatation of the colon and some loss of the haustral markings can also be seen.

Pseudomembranous colitis produces thickening of the colonic wall and changes in the lateroconal fascia and the perirenal fascia. The entire colon usually is involved, but there may also be segmental involvement.

Diverticulitis consistently shows changes recognizable on the CT scan.^{44, 66} First, small air pockets that represent air-filled diverticuli are seen on the wall of the colon.

Inflammation from the diverticulitis produces edema in the fat adjacent to the bowel.

Appendicitis produces edema and inflammation adjacent to the end of the cecum. The normal appendix can be located in the peritoneum, pelvis, or retrocecal region. With inflammation, there is edema and thickening of the adjacent fascial planes.

Whipple's Disease

A single report exists in the literature about Whipple's disease of the small bowel.⁶⁴ Clinically the disease is associated with abdominal pain, malabsorption, and diarrhea. Some arthralgias may also be associated. In a report by Li and Rennie,⁶⁴ the specific diagnostic points included enlarged lymph nodes in the 2- to 3-cm range in the mesentery and retroperitoneum. In addition, abnormal changes in the small bowel pattern similar to the findings noted on traditional barium studies were noted. The lymph nodes were low in density because of fat content. Some had necrosis within the center (see Chapter 35).

Amyloidosis

Systemic amyloidosis consists of systemic deposition of amyloid throughout organs and tissues. GI involvement is said to occur in 70% of patients with primary and 55.5% with secondary amyloidosis.²

A single report exists in the literature about the findings of secondary amyloidosis of the mesentery. In the case reported by Allen and colleagues,² there was diffuse thickening of the mesentery and encasement of the mesenteric vessels, resulting in the appearance of diffuse carcinomatosis. Diagnosis can be established only by biopsy (see Chapter 35).

Figure 42-58. A, Retractable mesenteritis produces a thickening of the mesentery (arrow), which may retract loops of the bowel posteriorly. (Compare the posterior location of these bowel loops with those pictured in Fig. 42-63C.) B, A mass (curved arrows) with calcifications (small arrows) caused by retractile mesenteritis. (B, courtesy Dr. Richard Palmer Gold, Columbia-Presbyterian Medical Center, New York.)

AIDS

AIDS is becoming more significant because of its almost uncontrolled spread among certain risk groups.^{13, 48} It is caused by the human immunodeficiency virus (HIV). Identified risk factors include homosexuality, IV drug abuse, and heterosexual exposure to prostitution.

These patients are at great risk for development of any infectious process, including many opportunistic infections. In addition, they are predisposed to the development of a number of malignancies, including Kaposi's sarcoma and a severe form of large cell lymphoma.

Jeffrey and coworkers⁴⁸ wrote an excellent article about AIDS within the abdomen. A review of this article is highly recommended for more specific details.

AIDS-related complex (ARC) is a constellation of symptoms and signs that predate the development of AIDS. Symptoms include fever, weight loss, diarrhea, malaise, and night sweats. There is associated lymphadenopathy in the mesentery and retroperitoneum secondary to reactive lymphoid hyperplasia. The triad of CT findings previously

Figure 42-59. Diffuse metastatic disease to the peritoneum may produce thickening of the mesentery that produces changes similar to those of retractile mesenteritis. This CT scan of a patient with metastases to the mesentery shows increased density to the mesentery with retraction of the bowel so that the loops do not float against the anterior peritoneum (arrow).

reported for this entity are lymphadenopathy, splenomegaly, and perirectal thickening (presumably owing to venereal infection). The lymph nodes in this state are seldom larger than 1.5 cm in diameter; any enlargement beyond this should suggest neoplasm or infection and probably warrants a CT-guided biopsy.

Opportunistic infections with AIDS are common and can consist of many forms, including *Candida* esophagitis and small bowel or colon infection with *Cryptosporidium*, cytomegalovirus, herpes simplex, or *Mycobacterium avium-intracellulare*. These problems cause nonspecific changes in those portions of the gastrointestinal tract. Both tuberculosis and *M. avium-intracellulare* can produce enlargement of mesenteric and retroperitoneal lymph nodes.^{84, 108}

The two most common malignancies associated with AIDS include Kaposi's sarcoma and non-Hodgkin's lymphoma. Kaposi's sarcoma can show lymphadenopathy or GI involvement in the form of wall thickening. It may involve virtually any abdominal organ and may produce many unusual intra-abdominal lesions, which may be easily amenable to CT procedures.

The lymphoma associated with AIDS usually is a non-Hodgkin's type (Hodgkin's disease occasionally occurs), which typically has an increased incidence of extranodal involvement. Sites of occurrence may include brain, bone marrow, viscera, and mucocutaneous sites. The lymphoma is especially aggressive, and response to treatment has been generally poor.

Neoplastic Lesions

Peritoneal Mesotheliomas

Peritoneal mesothelioma is a rare neoplasm arising in the peritoneal lining of the abdomen. The disease is be-

Figure 42-60. Extensive soft tissue thickening in the anterior abdomen produced by mesothelioma (*arrow*). The tumor is infiltrating throughout the mesentery in an irregular pattern.

Figure 42-61. CT scan of a patient with primary papillary carcinoma of the peritoneum. There is a fluid density anteriorly (*arrow*), which represents a neoplastic loculation.

lied to be associated with exposure to asbestos. Pathologically, it occurs in several forms: sarcoma, polygonal cell type, and tubular papillary type. All types have a uniformly poor prognosis, and most patients die within 2 years of the diagnosis. In my experience, the appearance of the tumor coincided with the timing reported in the literature.

On CT examination, (Fig. 42-60)¹⁷ the tumor appears as an area of soft tissue density within the abdomen. It may conform to the contour of the liver or produce a mass effect on adjacent structures. No features distinguish it clearly from other types of benign or malignant tumor with a benign fibrotic reaction. A number of authors have recommended signs for suggesting the diagnosis of mesothelioma.^{10, 85, 115, 118}

Primary Papillary Tumors of the Peritoneum

Since 1976, primary papillary tumor of the peritoneum has been recognized as a separate entity, although for a time, it was thought to be related to either mesothelioma or ovarian tumors.^{51, 90}

The tumor is thought to originate from mesothelial cells of the peritoneum, which are somewhat similar to ovarian cells. Clinical presentation of the patients is related to the involvement of multiple areas of the peritoneum. It is not possible to distinguish a metastatic focus from a localized origination point; the possibility of multicentric origin has been suggested.⁵¹ The disease in patients having these tumors is consistently more extensive than in patients of the same age who have ovarian tumors.

Treatment of the disease is similar to that of disseminated ovarian tumor. The outcome has not been good.

CT findings of this disease are nonspecific. Scans may show a discrete tumor mass over the peritoneum or simply collections of loculated fluid (Fig. 42-61).

Lymphomas

According to Goffinet and colleagues,²⁵ 61% of the non-Hodgkin's lymphomas involve the mesentery, whereas only

5% of Hodgkin's lymphomas do so. When involved, the mesentery contains a mass of soft tissue density, which may extend from the bowel loops to the root of the mesentery and the retroperitoneum (Fig. 42-62). The normal mesenteric vessels are not clearly seen in such cases. In other cases, there may be localized masses within the mesentery adjacent to loops of bowel. To diagnose small mass lesions, it is important to attempt total opacification of the bowel loops with either iodine or dilute barium solution. Even if this opacification is not total, such lesions can be distinguished in a normal bowel by a sufficiently characteristic appearance with fluid and gas.

After treatment, the tumors shrink gradually, but they may leave residual fibrous tissue. Such tissue may be prominent but should not be confused for active tumor. Treatment of such masses is usually continued until no interval shrinkage occurs in the mass.

Primary Mesenchymal Tumors

A variety of tumors that have no specific traits, except liposarcoma, originate from mesenchymal origin. Virtually

Figure 42-62. Lymphoma. CT scan shows a large soft tissue mass (*arrow*) in the root of the mesentery. The tumor extends to the wall of the small bowel, which is quite thick. Even when the bowel is distended, the mucosal markings can be seen.

Figure 42-63. Liposarcoma varies in its density depending on the degree of differentiation. Mesenchymal tumors may have a variable appearance, but liposarcomas are somewhat typical, as can be seen in the following scans. *A*, The well-differentiated liposarcomas (S) appear low in density, as does normal mesenteric fat. *B*, This scan shows a well-defined, higher-density tumor (S) that has an intermediate differentiation. *C*, This scan shows a poorly differentiated liposarcoma, with myxoid changes. It is producing a pseudomyxomatous invasion of the peritoneum. The loops of the small bowel (curved arrow) are compressed centrally by the low-density tumor, which appears almost like fluid. The bowel does not float as with normal ascites. The contrast-filled small bowel is compressed posteriorly on the left.

all such tumors show soft tissue density without any distinguishing features. Well-differentiated liposarcoma can show a fat density that is indistinguishable from normal fat (Fig. 42-63), whereas poorly differentiated tumors are slightly higher in density.

Metastatic Disease

Metastatic involvement of the omentum and mesentery is quite common with neoplasms,¹² the most common being from the ovary, stomach, pancreas, and colon.⁴⁷ Spread within the peritoneum can be along the surface of the peritoneum or within the ligaments (areolar tissue surrounded by peritoneum), which contain the lymph nodes draining a specific area. Lymphatic spread can occur along the neurovascular muscular bundles within the intermesenteric space. When fibrosis is associated with the lesions, there may be retraction in the mesentery.

When metastatic lesions are on the peritoneal surface, several findings may be noted. First, if they are large enough, they may be seen as discrete nodular lesions (Figs. 42-64 to 42-66). If the tumor is of mucinous origin, such as ovary or colon, it may show soft tissue or fluid density. When the sizes of the lesions are below the resolving power of CT, collections of fluid indistinguishable from any other fluid may be produced. The metastatic sites of the ovarian tumor can be completely fluid in appearance.⁷⁷ In such cases, the tumors may have the appearance of

Figure 42-64. Peritoneal tumor implants are more likely to occur along the undersurface of the diaphragm because of the anatomic structure of the peritoneum. CT scan shows small tumor implants (arrows) on the undersurface of the diaphragm.

Figure 42-65. Small tumor implants (*arrows*) are noted under the anterior surface of the left diaphragm. Without fluid loculation, they are more difficult to appreciate.

subcapsular collections or they may implant on specific ligaments such as the falciform ligament (Fig. 42-67).

Regardless of size, mucinous or other treated tumors can produce small calcifications throughout the peritoneum.⁸⁷ Mitchell and colleagues⁸² reported a series of 15 patients with carcinoma of the ovary and found calcifications in six peritoneal sites of implant, perihepatic calcifications in five sites, and lymph node calcifications in one (Fig. 42-68).

Making the diagnosis of a peritoneal metastasis can be difficult at times if the mass is not big enough to cause displacement of the bowel and if total opacification of the bowel has not been achieved.¹¹² The normal bowel, how-

Figure 42-67. Certain tumors, such as ovary and stomach, are thought to have a propensity for the falciform ligament (*arrow*).

ever, does have a characteristic appearance that shows small amounts of fluid and gas in a diffuse pattern. Sometimes, even after administration of contrast material, there may be a problem distinguishing an adynamic loop of bowel from a mass. In such cases, IV administration of contrast material may be helpful because the wall of the bowel enhances well, or placing the patient in a decubitus position permits moving “gas” to reveal the true nature of a loop of bowel.

Omental Changes

The thickened omentum produced by “caking” appears as a large soft tissue mass with poorly defined edges. The fat plane between the anterior abdominal wall and the intestinal loops may be obscured. When the omentum (which shows fat density) is not thick, soft tissue masses within or on it may be seen.

Figure 42-66. Omental metastases. A, Early tumor implantation on the omentum produces small masses (*arrows*) throughout the anterior peritoneum. B, More extensive tumor implantation produces a thick soft tissue density (*arrows*), displacing the colon from the anterior peritoneum.

Figure 42–68. On occasion, mucinous or necrotic tumors contain dystrophic calcifications. Note the high-density material on the posterior right hepatic lobe, porta hepatis, and posterior spleen.

Sites of Implants

It has been suggested that the ligaments at the reflection of the sigmoid colon, the ileocolic region, and broad ligaments are the first location of implantation with malignancy.^{79, 103, 114} Data have shown, however, that for the earliest detection of peritoneal seeding (at least with ovarian neoplasms), biopsy of the diaphragmatic areas is more likely to show early peritoneal involvement.²⁷ This is presumably a result of the circulation of peritoneal fluid. Common metastases of ovarian or gastric cancers to the falciform ligament may also be a result of this normal upward flow toward the diaphragm.

General Diagnostic Signs

Whitley¹¹⁵ has evaluated a group of 370 patients who had mesenteric tumors and recommended some diagnostic signs that are helpful in approaching mesenteric disease. The following diagnostic signs characterize the lesions according to their appearance: rounded, ill-defined, cake-like, and stellate.

Rounded masses were caused by non-Hodgkin's disease in 33 of 41 cases, leukemia in 2 of 26 cases, and ovarian tumor in 3 of 38 cases. Whitley also noted a 30% occurrence in the nodes of the small bowel mesentery.¹¹⁵ Other authors have noted an overall occurrence of 50% if nodes at the root of the mesentery are included.

Ill-defined masses, the next most common type of involvement, occurred in 27 patients. Of this group, the non-Hodgkin's and ovarian carcinomas were the most common type of involvement, followed by colon, pancreas, stomach, and other masses.

Cakelike masses of the mesentery occurred with ovarian tumors, non-Hodgkin's lymphoma, and leukemia.

Stellate infiltration of the neurovascular bundles of the mesentery occurred with all types of metastatic disease except lymphomas and leukemia. The stellate pattern is produced by the infiltration along the inner margins of the mesentery.

Levitt and coworkers⁶¹ reported the detection of metastases in 18 of 27 cases. They noted that CT did not show

microscopic lesions, masses smaller than 1 cm, or omental metastases, such as pancreatic and gastric carcinomas that are immediately adjacent to primary masses.

An article by Goldhirsch and colleagues²⁷ indicates that CT was not as accurate as second-look surgical exploration. A positive CT scan is a useful guide for the surgeon, but a negative study does not obviate the need for a second-look surgical procedure.

Early authors used contrast peritoneography to demonstrate the normal peritoneal spaces.⁹³ More recently, workers have used positive contrast as a method of clearly defining small peritoneal implants especially close to the diaphragm.¹⁰⁷

Pseudomyxoma Peritonei

Pseudomyxoma peritonei is a rare disease resulting from the diffuse dissemination of mucinous material derived from neoplasms. Typically, the neoplasms producing the peritoneal seeding are mucinous cystadenocarcinomas of either the ovary or the appendix, but it may occur unusually with tumors of the urachus, uterus, or omphalomesenteric duct. The disease is quite indolent, and massive deposition of material may occur before it is noticed. On CT scans, this seems to have two appearances.^{71, 74, 77, 100, 113} It may appear as discrete, low-density cystic masses located in multiple anatomic spaces. In other cases, the peritoneum is completely filled and resembles ascitic fluid, sometimes producing mass effects on adjacent organs. Calcifications may occur following chemotherapy.⁸¹

Carcinoid Tumors

A carcinoid is a serotonin-producing tumor commonly involving the terminal ileum; it can produce changes within the mesentery, creating a desmoplastic fibrotic reaction. If the tumor is small or microscopic, no abnormality is seen on the scan. If a significant desmoplastic reaction occurs, however, there may be thickening of the mesentery with areas of soft tissue density. By the time the disease is first seen, there are liver metastases, which also may be an associated finding on CT scans.

The Retroperitoneum

Ashok K. Gupta, Richard H. Cohan

The retroperitoneum is that portion of the abdomen located posterior to the peritoneal cavity. It extends from the diaphragm to the pelvic inlet and includes portions of the colon, duodenum, pancreas, kidneys, adrenal glands, abdominal aorta, inferior vena cava (IVC), lymph nodes, fat, and much of the abdominal wall musculature.⁹⁴

Cross-sectional imaging has had a profound effect on the diagnosis and treatment of retroperitoneal diseases. This chapter presents the computed tomography (CT) and magnetic resonance imaging (MRI) appearances of normal retroperitoneal anatomy. CT and MRI manifestations of abnormalities involving the retroperitoneal spaces, aorta, IVC, and retroperitoneal lymph nodes are described and illustrated. Disease processes confined to the retroperitoneum, including primary retroperitoneal tumors, retroperitoneal fibrosis, and abnormalities related to the iliopsoas muscles, are also discussed.

Retroperitoneal Spaces

Normal Anatomy

The retroperitoneum is commonly divided into three spaces by the anterior and posterior renal fasciae (Fig. 43-1).¹²⁹

The *anterior pararenal space* is bordered anteriorly by the parietal peritoneum, posteriorly by the anterior renal fascia (Gerota's fascia), and posterolaterally by the lateral continuation of the renal fasciae and the lateroconal fascia. This space contains the pancreas, retroperitoneal portions of the duodenum, and ascending and descending colon.¹²⁹

The *perirenal space*, the largest retroperitoneal compartment, lies within the anterior and posterior renal fasciae and contains the kidneys, adrenals, proximal renal collecting systems, and renal hilar vessels.²¹⁰ The perirenal fasciae fuse medially and blend with the retroperitoneal fat surrounding the great vessels and adjacent lymph nodes. The perirenal spaces therefore theoretically communicate with one another across the midline via a narrow potential space anterior to the caudal aspects of the aorta and the IVC.¹²⁹ The large amount of perirenal fat in the perirenal space is subdivided by bridging septa, which are often able to confine pathologic perirenal processes to portions of the perirenal space. These septa are thought to prevent most perirenal processes from spreading into the central retroperitoneum and crossing the midline to involve the contralateral perirenal space.²¹²

The *posterior pararenal space* is the smallest of the three retroperitoneal spaces. It is located posterior to the

posterior renal fascia and contains only a small amount of fat. Although it is located posterior to the kidneys, it continues anterolaterally.¹²⁹ Indeed, posterior pararenal space fat is responsible for the properitoneal fat stripe seen on plain abdominal radiographs.

The *psoas compartment*, sometimes considered a fourth retroperitoneal space, is located within and immediately adjacent to the psoas muscles. It is immediately adjacent to the posteromedial aspect of the posterior pararenal space.

Some controversy exists about whether the retroperitoneal spaces communicate with the pelvis. Some communication has always been suspected, since pelvic hematomas have been observed to extend cephalad into abdominal retroperitoneal tissue. It has long been thought that the inferior aspect of the perirenal space is open, allowing this space to freely communicate with the other retroperitoneal spaces and the retroperitoneal tissue in the pelvis.¹²⁹ This was apparently confirmed in a study of cadavers imaged with CT, in which injected contrast material was found to track caudad from the perirenal space into the extraperitoneal spaces of the pelvis.¹⁶⁹ Communication between the anterior and posterior pararenal spaces and the pelvic extraperitoneum was also demonstrated.

In contrast, when Raptopoulos and colleagues injected latex into the perirenal spaces of cadavers, they found that none of the latex tracked into the pelvis, suggesting that the inferior aspect of the perirenal space is closed.²¹¹ It has been postulated that this discrepancy may be explained on the basis of the ability of fluid within closed retroperitoneal

Figure 43-1. Anatomy of the retroperitoneum. 1, anterior perirenal fascia; 2, lateroconal fascia; 3, posterior perirenal fascia; 4, bridging septa in the perirenal space; A, aorta; I, inferior vena cava.

spaces to track inferiorly by entering the easily dissected planes between these spaces. It is these planes that freely communicate with the pelvic extraperitoneum.¹⁷¹

Pathologic Conditions

Identification of the retroperitoneal spaces in which retroperitoneal masses or fluid collections are seen on CT and MRI examinations may help elucidate their causes. Because the anterior and posterior renal and lateroconal fasciae are identified on CT and MRI as pencil-thin, linear, soft tissue densities enveloping the perirenal fat and extending toward the, lateral abdominal wall, the retroperitoneal spaces are usually easily identified.¹²⁹

Fluid collections in the anterior pararenal space often result from pancreatitis or hematomas (Fig. 43-2). Although these commonly involve only one side of the retroperitoneum, they may spread across the midline. This is particularly seen in patients with pancreatitis.²¹⁰

Abscesses, hematomas, urinomas, and neoplasms can all develop in the perirenal space. In most cases, these are the result of abnormalities of the kidneys, adrenals, or proximal renal collecting systems, although extension from the aorta and pancreas is also common. Perinephric space hemorrhage is usually caused by blunt trauma (Fig. 43-3), a ruptured abdominal aortic aneurysm (AAA), or bleeding from a renal mass.^{21, 129} Abnormal perirenal space fluid may be in either of two locations: within the renal capsule (subcapsular) or outside the capsule in the perinephric fat.

These two types of fluid collections can often be differentiated from one another. Subcapsular fluid collections usually produce distortion of the renal parenchyma, whereas perinephric collections do not. Unfortunately, there is frequently overlap. This is because when a perinephric fluid collection develops between the renal capsule and the posterior renorenal septum (one of the bridging perinephric septa), the renal parenchyma may be compressed and the CT or MRI appearance may be indistinguishable from that of a subcapsular hematoma.¹²⁹

Figure 43-2. Fluid in the anterior pararenal space. Intravenous contrast-enhanced CT scan in a patient with acute pancreatitis demonstrates peripancreatic fluid in the left anterior pararenal space.

Figure 43-3. Fluid in the perirenal space. Delayed contrast-enhanced image through the midabdomen of a patient who sustained blunt abdominal trauma and injury to the renal collecting system shows accumulation of contrast-enhanced urine in the right perirenal space (arrows). A portion of the urinoma also extends into the right anterior pararenal space (arrowheads).

Abnormalities in the posterior pararenal space are much less common than abnormalities in the anterior pararenal space or the perirenal space. When present, these are most commonly the result of spread of pathologic processes in the pelvis. Causes can include hematoma (Fig. 43-4), infection, and neoplasm. In a minority of patients, peripancreatic fluid or phlegmon may spread through or around the fascial layers into the posterior from the anterior pararenal space.

Localization of retroperitoneal fluid within one of the major compartments is sometimes difficult. This is nowhere more apparent than in the retrorenal region. Retrorenal collections may reside within any of the retroperitoneal

Figure 43-4. Fluid in the posterior pararenal space. Unenhanced CT scan of the right posterior pararenal space in a patient given anticoagulation agents demonstrates a fluid-fluid level within a large hematoma. The fluid displaces the posterior perirenal fascia (arrow) anteriorly. Intrapertoneal fluid is also present (arrowhead).

spaces.¹²⁹ In some patients, the anterior renal fascia, posterior renal fascia, and lateroconal fascia meet in a more dorsal location, and this results in a portion of the anterior pararenal space lying posterior to the kidney. Also, perirenal fluid can layer in front of or behind the kidney.

Because the anterior, posterior, and lateroconal fasciae are often not seen as three distinct layers but instead as a multilayered complex, fluid may migrate within the leaves of this fascial network.²¹⁰ Some inflammatory processes, such as pancreatitis with its proteolytic enzymes and neoplasms, can destroy fascial barriers, further complicating attempts at fluid localization. In addition, the paracolic gutters of the peritoneal cavity occasionally may extend posterolateral to the kidney.¹²⁹ Thus, intraperitoneal fluid may also occasionally have a retrorenal location.

Inflammatory and neoplastic processes in any of the three major retroperitoneal spaces can cause thickening of the retroperitoneal fasciae. This response is nonspecific, and even in patients with an adjacent malignancy it does not necessarily indicate infiltration of these layers with tumor cells.

Aorta

Normal Anatomy

The aorta extends from the diaphragmatic hiatus to the level of the umbilicus or fourth lumbar vertebral body, where it bifurcates into the two common iliac arteries. The normal aorta is located just to the left of midline and is surrounded by retroperitoneal fat. In one autopsy series, the mean diameter of the normal infrarenal abdominal aorta was 1.75 cm for men and 1.64 cm for women.⁵² The aorta usually enlarges as individuals age. In the same series, the mean "normal" aortic diameters for men and women between 19 and 29 years of age were 1.51 and 1.39 cm, respectively; those for men and women between 80 and 92 years of age were 1.96 and 1.82 cm.⁵² Generally, a normal-caliber abdominal aorta never exceeds 3 cm in maximal diameter.⁴⁵

The aorta is easily visualized on abdominal CT and MRI examinations. The celiac, superior mesenteric, and inferior mesenteric artery origins can also be identified in most patients. The renal arteries are less reliably visualized on routine abdominal and pelvic studies, but they are easily detected when CT or MR angiography (MRA) is performed. CT or MRI measurements of the abdominal aortic caliber are comparable to those obtained in autopsy series. On CT, for example, the mean normal aortic diameter at the level of the renal hilum has been measured to be between 1.5 cm in women in their fourth decade and 2.1 cm in men in their eighth decade. Mean infrarenal aortic diameters are 1.4 cm and 2.0 cm in the same two patient populations.²³³

Abnormalities of the Abdominal Aorta

The most important abdominal aortic abnormality is aneurysm formation and its consequences (aortic rupture). The ensuing paragraphs review the imaging of aortic aneurysms and patients with suspected aneurysm ruptures. The

CT and MRI appearances of aortic dissections extending into the abdominal aorta and with penetrating ulcers are also reviewed. The significance of the small aorta is addressed. Imaging of the treated abdominal aortic aneurysm, including the appearance of normal surgical grafts and endovascular grafts and of complications of graft insertion, is also provided.

CT and MRI Technique

With CT, the aorta can be identified on either routine noncontrast or dynamic bolus contrast-enhanced scans obtained at contiguous 7- to 10-mm intervals through the abdomen. When detailed evaluation of the aorta is required, however, CT arteriography is most helpful. For CT arteriography, a dynamic bolus injection of contrast material, 60% by weight, is administered by a mechanical injector at a rate of 4 to 5 mL/second. After a delay of 25 to 40 seconds, thinly collimated (2.5- to 3-mm-thick) images are usually obtained. Images may then be reconstructed at overlapping intervals (usually with 50% overlap) so that three-dimensional (3D) reconstructions can be obtained.

Helical scanning is essential. CT angiography cannot be adequately performed when conventional axial scanners are used because of the lengthy time required for image acquisition and the large number of images that must be obtained. The most thinly collimated images can be obtained most rapidly on the new multidetector CT scanners, on which hundreds of images can be generated in less than 30 seconds. Indeed, the advent of multidetector helical CT has revolutionized CT angiography allowing it to compete successfully with both conventional and MR angiography.

Once helically obtained axial images are acquired, 3D reformatted images can be created with the use of a workstation to which the obtained images are forwarded. Excellent-quality images can be reconstructed in a variety of formats (standard coronal and sagittal planes, oblique planes, curved multiplanar images, and a variety of 3D techniques); however, today the most popular 3D reconstruction algorithms for visualization of the aorta are maximum intensity projection and volume-rendered images. Three-dimensional image reconstructions can be created from the entire data set or from a portion of the data set. Although 3D image reconstruction was time-consuming in the past, improvements in computer software and hardware now allow for images to be created in less than 10 minutes. Modifications have been made to the shaded-surface display and volume-rendered techniques such that both calcifications in the aorta and the surface of the aorta can be visualized together. Angioscopic images can also now be created.²³⁷

It must be emphasized that all of the information is on the retrospectively obtained (usually overlapping) axial images. These can be accurately interpreted by careful review of the images in a cine loop on the console. Furthermore, information can be lost on reconstructed images, leading to erroneous diagnoses, so that 3D reconstructions must be carefully created by knowledgeable and experienced radiologists or technologists.²³³

One potential drawback of CT arteriography is a relatively large intravenous (IV) bolus of potentially nephro-

toxic contrast material is required (with volumes of injected contrast material usually approaching 150 mL of 60% by weight contrast media). Concerns about nephrotoxicity are substantial in this patient population because many patients with aortic disease have associated severe renovascular disease.

Some researchers have responded to this concern by performing CT arteriography after administration of the MRI contrast agent gadopentetate dimeglumine. Gadopentetate dimeglumine is, in fact, more radiopaque than iodinated contrast material. It has a significantly higher rate of x-ray absorption than does the same concentration and volume of iodinated radiographic contrast media. Unfortunately, much lower total doses of gadopentetate (in comparison with iodinated contrast media) have been approved for intravascular use. When these lower doses are used, vessel radiopacity is generally much less than that seen after injection of standard volumes of iodinated contrast material.²⁰⁰ This limits the quality of CT arteriography performed with this MRI contrast agent.

MRA is best performed on a 1.5-tesla (T) magnet with a body coil. The protocol used at the University of Michigan Hospital is as follows. Initially, T1-weighted (TR = 333 msec, TE = 25 msec) sagittal images can be obtained for localization. Then, an IV injection of 42 mL (two bottles) of gadolinium chelate is administered while a coronal 3D spoiled gradient-echo sequence is performed (TR = 24 msec, TE = 6.9 msec; flip angle = 40 degrees; bandwidth = 16 kHz; 28 slices with 2.5- to 2.8-mm thickness; matrix 256 × 256; frequency encoding, superior to inferior; flow compensation; field of view = 36 cm; 1 NEX). Subsequently, sagittal 2D time-of-flight, axial 2D time-of-flight, and 3D phase-contrast images can be obtained. The 3D images obtained with MRA can be processed in a fashion similar to those acquired during CT arteriography (Fig. 43-5). Of course, MRA cannot be performed if there are contraindications (e.g., presence of an indwelling pacemaker).

Aortic Aneurysms: Prevalence, Growth, and Imaging Appearance

Abdominal aortic aneurysms (AAAs), defined as focal areas of aortic dilatation that usually exceed 3 cm in maximal diameter, occur in 1% to 4.5% of older adults.^{75, 221, 227} It has been thought that most AAAs result from atherosclerosis; however, it is now postulated that these "atherosclerotic" aneurysms actually form as a result of an inflammatory process in the aorta that leads to plaque formation and vessel dilatation. It has been suggested that the term *atherosclerosis* be replaced with the term *degenerative* or *nonspecific* in reference to these most commonly encountered types of aortic aneurysms.⁸² Other causes of aortic aneurysms include trauma, infection, cystic medial necrosis, Marfan's syndrome, Takayasu's arteritis, and syphilis.¹³⁵ AAAs are often asymptomatic, although patients may present with a pulsatile abdominal mass.⁷⁹

Most AAAs originate below the level of the renal arteries. Between 2% and 20% of AAAs are believed to be *juxtarenal* (extending to within 1.0 to 1.5 cm of the renal artery origins but not involving these vessels) or *pararenal*

Figure 43-5. Normal aorta in a 28-year-old man. Magnetic resonance angiogram shows that the aorta is smoothly contoured and tapers gradually to the level of the aortic bifurcation.

(involving one or both renal arteries).⁶⁵ It is indeed fortunate that most aneurysms are infrarenal, because surgical repair of juxtarenal and pararenal aneurysms is much more complex than repair of infrarenal aortic aneurysms and patient morbidity and mortality are higher.⁶⁵ Also, standard endovascular stent-graft insertion is not possible when aneurysms are juxtarenal or pararenal.

Over time, at least 80% of AAAs enlarge.⁶⁴ Unfortunately, it is not possible to predict which detected aneurysms will enlarge and which will remain stable. Most aneurysms enlarge slowly. Larger aneurysms usually enlarge at a more rapid rate than smaller aneurysms. In general, aneurysms measuring 5 cm or more in maximal diameter enlarge by 4 to 8 mm per year. Aneurysms measuring between 4 and 5 cm in maximal diameter enlarge by 3 to 7 mm per year. Aneurysms measuring less than 4 cm in maximal diameter enlarge by 2 to 5 mm per year.^{28, 48, 86, 148}

AAAs are easily visualized with CT and MRI (Figs. 43-6 and 43-7). The aortic wall is at least partially calcified in nearly every patient in whom "atherosclerosis" was the cause of the aneurysm, and this calcification is easily visualized on CT scans.^{75, 154} CT-detected mural thrombus most often surrounds the patent aortic lumen but may be crescentic. Occasionally, an aneurysm thrombus may partially calcify, and this appearance may be confused with displaced intima in an aortic dissection.^{99, 154}

Inflammatory Aneurysms and Perianeurysmal Fibrosis

In 5% to 15% of cases, aortic aneurysms are surrounded by inflammatory or fibrotic tissue.^{57, 75, 213} This represents perianeurysmal fibrosis, which is believed to result from a fibrotic autoimmune reaction to material in atherosclerotic

Figure 43-6. Abdominal aortic aneurysm. Dynamic, intravenous contrast-enhanced CT scan demonstrates a large amount of thrombus within the aneurysm. Some of the thrombus is calcified. An arteriogram on this patient would significantly underestimate the size of the aneurysm because only the patent part of the lumen containing flowing blood would be opacified.

plaques.¹³⁰ Currently, most researchers believe that the process involved in the formation of these inflammatory aneurysms is similar to, but more extensive than, that involved in the formation of aneurysms that are not surrounded by any inflammation or fibrosis.^{55, 213} This is because similar inflammatory changes are found in the walls of both inflammatory and noninflammatory aneurysms.

Patients with inflammatory aneurysms may present with abdominal or back pain. The erythrocyte sedimentation rate (ESR) is often elevated. Treatment is similar to that of a noninflammatory aneurysm. Although the rupture rate is considered to be lower for inflammatory aneurysms than that encountered for comparably sized noninflammatory aneurysms (possibly because of the additional aortic wall thickening and the surrounding reaction), rupture may occur in these patients.⁵⁵ Thus, large aneurysms surrounded by perianeurysmal fibrosis must be repaired. Surgery in

these patients is difficult because of the extensive inflammatory and fibrotic changes in the retroperitoneum. After treatment of the aneurysm, the retroperitoneal changes regress in many patients.

Both CT and MRI can often, but not always, be used to detect perianeurysmal fibrosis (Fig. 43-8). In one study, CT allowed identification of perianeurysmal fibrosis in only 9 of 15 patients in whom this inflammatory reaction was subsequently identified at surgery.⁵⁶ In another study, CT was used to identify the fibrosis in 13 of 15 patients.⁵⁵

One report suggested that MRI may be more sensitive than CT in detected perianeurysmal fibrosis.²⁵⁰ In this series, CT was successfully used to identify the perianeurysmal changes in only 7 of 15 patients with inflammatory aneurysms, whereas MRI was 100% sensitive, detecting characteristic alternating bands of high and low signal intensity in the periaortic tissue on T1-weighted spin-echo images.²⁵⁰

Mycotic Aneurysms

Infected or mycotic aneurysms account for nearly 3% of AAAs. These aneurysms, which are usually encountered in IV drug abusers or immunocompromised patients, can be suspected if an aneurysm is identified in a patient who is unlikely to have atherosclerotic disease and who has a fever and leukocytosis. Recognition of mycotic aneurysms as a distinct group on CT scans or MR images is important because these aneurysms are more prone to rupture than comparably sized atherosclerotic aneurysms.

In a small series, Sueyoshi and associates found an increase in periaortic fat to be one of the earliest signs of aneurysm infection.²⁴⁵ Clearly, this finding can be assessed only when sequential CT scans are available. An aneurysm can also be suspected to be mycotic when its contour is irregular (Fig. 43-9), although most irregularly shaped aortic aneurysms are atherosclerotic.²³³ Rapid enlargement of an aneurysm (again, assessable only when more than one cross-sectional imaging study is available), lack of calcification, and unusual (noninfrarenal) location should also suggest a mycotic origin. Perianeurysmal air and enlarged

Figure 43-7. Supraceliac abdominal aortic aneurysm, as seen on a fat-suppressed, limited flip-angle MR image. There is no thrombus in this aneurysm.

Figure 43-8. Perianeurysmal fibrosis. Unenhanced CT scan shows a rind of soft tissue (arrows) surrounding the anterior and lateral aspects of a large abdominal aortic aneurysm.

Figure 43-9. Mycotic abdominal aortic aneurysm. A, CT scan of a left psoas abscess (A) in a 66-year-old man also demonstrates a mycotic aneurysm as a focal outpouching of contrast-enhanced blood from the left posterolateral aspect of the aorta (arrow). B, A digital subtraction image from an aortogram better demonstrates the irregular shape of this mycotic aneurysm (arrow).

retroperitoneal lymph nodes may be other accompanying signs suggestive of infection.

Abdominal Aortic Aneurysms: Are Some More Likely to Rupture?

Given long enough patient survival, virtually all enlarging aneurysms rupture. Repair of AAAs is strongly preferred prior to rupture because morbidity and mortality are much higher in patients undergoing emergency aneurysm repairs (after aneurysm rupture) than in those undergoing elective or semielective repairs. Interestingly, the operative mortality for elective aneurysm repair has decreased dramatically in the past few decades, to well below 10%, whereas the mortality for emergency aneurysm repair has remained stable, at more than 50% in some studies.^{233, 266} Long-term patient morbidity and mortality are also considerably higher after emergency aneurysm repair than after elective aneurysm repair.⁴⁰

According to many vascular surgeons, operative repair of AAAs is indicated when they exceed 5 cm in maximal diameter, since the tendency to rupture increases dramatically once aneurysms reach this size. In one series, the percentage of aneurysms measuring 5 cm in diameter that could be predicted to rupture in 1 year was 2.5%.²⁵⁹ In another, the maximum potential rupture rate (actual rupture rate plus elective surgery rate) for AAAs of 4.5 to 5.9 cm maximal diameter was found to be 10.2% per year.²²⁸ There are only isolated reports of ruptures occurring in smaller aneurysms.¹⁸⁶

Although patients with an aortic aneurysm 5 cm or greater in diameter and who are good operative candidates

should undergo surgical repair, patients with smaller aneurysms are usually monitored by serial ultrasound studies.²⁵⁸ Most recommend repeating the ultrasound examination every 6 months; however, because aneurysm growth is slow, aneurysm enlargement may not be detected unless the current study is compared with several previous examinations. Interobserver and intraobserver variability in measurements obtained during sonography can be substantial. The smallest measured difference in ultrasound-measured aneurysm diameter that has been found to reliably indicate true interval growth is 8 mm.²²⁹ This greatly exceeds the typical, expected 6-month growth rate of even the largest aneurysms. The variability in aneurysm measurement with sonography generally greatly exceeds that encountered with CT.¹³⁸

As an alternative to monitoring small aneurysms with sonography, some researchers now recommend surgical repair *before* the aneurysm reaches the threshold maximal diameter of 5 cm.^{12, 186} This is because operative morbidity and mortality rates may be lower for these generally younger and healthier patients, and aneurysm repair is easier to perform when the aneurysm is small.

A number of researchers have attempted to identify features in AAAs, aside from maximal diameter, that may indicate probability of rupture. If such features could be described, it might be possible to identify a subset of patients with AAAs, including aneurysms less than 5 cm in maximal diameter, in whom prompt surgery is indicated.

Several ominous imaging findings have been identified. As previously noted, mycotic aneurysms as a group are more likely than atherosclerotic aneurysms to rupture. If an aneurysm increases in size by 1 cm or more in maximal diameter over 6 months, the risk of rupture is thought to be greatly increased.²³³

Identification of a high-attenuation crescent within an aneurysm wall or in a thrombus on either unenhanced or IV contrast-enhanced CT scans may also indicate an increased tendency to rupture (Fig. 43–10). Mehard and colleagues identified a high-attenuation crescent in the thrombi or walls of AAAs in 19 of 149 unenhanced CT scans of patients before AAA repair.¹⁶² Ten of these 19 patients had frank AAA ruptures (4 patients), contained ruptures (3 patients), or intramural hemorrhage (3 patients) found during subsequent surgery. In only nine patients was no evidence of a rupture found on follow-up.

Siegel and colleagues found similar high-attenuation crescents in the thrombi of 11 of 52 patients with ruptured AAAs who were evaluated with either enhanced or unenhanced CT.²³² No such crescents were found in the thrombi of any of the 56 nonruptured aneurysms used as a control group. It is thought that the crescent is caused by dissection or leaking of blood into the thrombus or the wall of an AAA, an event that may be an early step in the development of a true aortic rupture.^{7, 226}

Whatever the cause, these studies suggest that when CT detects a high-attenuation crescent in the thrombus of an AAA or adjacent to the wall of an AAA, the patient should, at the least, receive careful follow-up. The likelihood of rupture occurring sooner rather than later may be higher than in patients whose aneurysms are not characterized by this finding.

Another finding that may indicate an aneurysm likely to rupture or one that has already ruptured is the *draped aorta sign*. In patients with this sign, the wall of the aneurysmally dilated aorta is not clearly visualized posteriorly, and the

posterior portion of the aorta is closely applied to one or several vertebral bodies and follows their contours on one or both sides. The aorta appears to be “draped over” adjacent vertebral bodies (Fig. 43–11). In one series of 10 patients whose CT examinations demonstrated this appearance, seven had contained leaks, two had weakened aortic walls resulting from a mycotic aneurysm, and the final patient had an anastomotic pseudoaneurysm (which developed after aortic graft surgery).⁹²

Several other features, including aneurysm and thrombus shape, amount of thrombus, and amount or distribution of wall calcification, do not appear to be related to the tendency of an aneurysm to rupture.²³³

Preoperative Evaluation of Abdominal Aortic Aneurysms

CT angiography and MRA have gradually replaced aortography as the procedures of choice for preoperative imaging of AAAs.^{223, 233} This is the case for patients who are being considered for standard aneurysm repair and for those who are poor operative candidates and in whom an endovascular stent-graft is being considered. Preoperative assessment of AAAs with CT or MRI is valuable for delineation of proximal and distal extent, determination of maximal aneurysm diameter, detection of venous anomalies, and assessment of the periaortic tissues (for perianeurysmal fibrosis).²²³ CT angiography and MRA can also accurately determine the number and locations of the renal arteries and the presence of any renal artery stenoses, or iliac artery stenoses and aneurysms.²²³

As previously stated, although most aneurysms are infrarenal, demonstration of renal artery involvement is cru-

Figure 43–10. Large abdominal aortic aneurysm with crescent sign. Contrast-enhanced CT scan shows a crescent of high attenuation (arrows) in the aneurysm thrombus. This finding is believed to indicate that the aneurysm is likely to rupture in the near future. Indeed, rupture has already occurred, as evidenced by the poorly defined hematoma (arrowhead) located peripheral to calcification in the aortic wall.

Figure 43–11. Draped aorta sign. Contrast-enhanced CT scan in an elderly man shows a large abdominal aortic aneurysm that appears to be draped over the adjacent lumbar vertebral body. The fat plane between the aorta and the vertebral body has been obliterated. This finding is ominous and indicates that free aneurysm rupture is likely in the near future.

cial, as this indicates that subsequent surgery will be much more complicated. Additionally, extension into the iliac arteries, discrete iliac artery aneurysms, or atherosclerotic occlusive aortoiliac disease may require the insertion of a Y graft rather than a simple aortic graft.¹³⁹

CT angiography, with rapid bolus IV injections of contrast media and helical scanning, can provide images that are nearly as good as those obtained with angiography, especially if multidetector helical CT technology is used and if 3D reconstructions are obtained (Fig. 43-12). CT angiography technique has already been described (see "CT and MRI Technique").

CT and CT angiography measurements of aneurysm

diameter and aortoiliac length are highly accurate, with interobserver variability being minimal.⁸ In one study, interobserver variability in aneurysm diameter, measured by radiologists in the same department, exceeded 2 mm in only 10% of patients.¹³⁸ Furthermore, CT angiography also accurately identifies accessory renal arteries and vascular anatomic variants.²²³ These findings confirm that CT angiography can completely replace aortography and produces accurate images of AAAs, before both open surgery and endovascular stent-graft insertion.

MRA evaluation of AAAs (see Fig. 43-7) is probably just as diagnostic as CT and can also be performed instead of conventional arteriography.^{201, 206} In a study of 43 pa-

Figure 43-12. Abdominal aortic aneurysms, 3D CT reconstruction images. *A*, Sagittal reformatted image of a large infrarenal abdominal aortic aneurysm demonstrates that the aneurysm begins well below the level of the origins of the celiac axis and the superior mesenteric artery. *B*, Shaded-surface display image in the coronal plane (with subtraction of overlying osseous structures) shows the same aneurysm to originate well below the level of single renal arteries bilaterally. *C*, Volume-rendered image in another patient reveals another infrarenal abdominal aortic aneurysm. The reconstruction algorithm here allows for two different thresholds to be used: a *lower*-attenuation threshold to determine the aortic caliber and a *higher*-attenuation threshold for aortic wall calcification.

tients with AAAs who underwent aneurysm repair, Prince and colleagues found that AAA extent was properly delineated in all patients.²⁰⁷ MRA also revealed significant arterial stenoses, with a 94% sensitivity and a 98% specificity. The authors also point out some advantages of MRA over CT angiography, including the lack of ionizing radiation and the lack of need for administration of potential nephrotoxic iodinated contrast material.

In another study, MRA was found to be significantly better than conventional axial (nonhelical) CT at imaging the AAAs of 82 patients before endoluminal stent-graft insertion.¹⁸³

Ultrasonography is not used for preoperative evaluation of AAAs. It cannot reliably assess the periaortic tissue, and it occasionally is able to only imply the relationship of the aneurysm to the renal arteries because the latter are not always visualized. Because the superior mesenteric artery originates in close proximity to the renal vessels, an aneurysm may be presumed to be infrarenal if it begins more than 1.5 to 2 cm caudad to this artery, even when the renal arteries cannot be imaged.

Aortic Aneurysm Rupture

Aneurysm leak or rupture is a catastrophic event. If the rupture is untreated, mortality is 100%. Only about 50% of patients survive long enough to be admitted to the hospital.¹¹⁸ Emergency aortic aneurysm repair is indicated in any operative candidate, since the alternative is certain death. Even when surgery is performed, patient survival is poor, with between 30% and 65% of patients still living at 30 days.^{30, 118} Traditionally, emergency aortic aneurysm repair usually involves prompt transfer to the operating room, rapid clamping of the aorta to establish hemostasis, usually at the level of the diaphragm, and then aortic graft insertion. Endovascular stent-graft insertions have been performed successfully in patients who are poor operative risks.¹⁹¹

A patient presenting with abdominal or back pain, a pulsatile mass (thought to be an aortic aneurysm), and severe hypotension should proceed directly to surgery. Many vascular surgeons also recommend that when the diagnosis is certain clinically (i.e., the patient has a known large AAA and abdominal pain), the patient should proceed directly to the operating room even if he or she is hemodynamically stable.^{46, 233}

Unfortunately, only a minority of patients with ruptured aneurysms come to the emergency department with the classic triad of symptoms,²³³ and only slightly more than half have characteristic acute back or abdominal pain or both.² Conversely, in many patients thought to have a ruptured aneurysm, other causes of abdominal pain are ultimately identified. In one series, only 18 of 65 stable patients with suspected aneurysms and abdominal pain had AAA ruptures.¹³³ Initial misdiagnoses (with false-negative as well as false-positive clinical diagnoses) can occur in as many as 60% of patients.² For this reason, CT is recommended as the procedure of choice for evaluation of hemodynamically stable patients with a suspected aneurysm when other diagnoses are also considered. Although some authors (Buss and coworkers³¹) disagree, it is generally

believed that the delay imposed by obtaining a rapid, emergency CT scan in appropriately selected patients does not adversely affect patient morbidity or mortality.¹³³

CT is quite sensitive in detecting aortic ruptures and can also identify other causes of abdominal pain in some patients when ruptures are not present. In addition to revealing whether a rupture is present, the CT scan can be used to assess the size and extent of an AAA. In fact, it may even be used to predict whether a ruptured aneurysm is infrarenal, juxtarenal, pararenal, or suprarenal.⁴⁶

CT is preferred over MRI for imaging of a suspected ruptured aneurysm, because gravely ill patients are generally managed much better in the CT suite. CT technique in these patients requires only that a rapid examination be performed. Use of oral contrast material may be helpful for distinguishing duodenum from periaortic hematoma in a few patients; however, this is not commonly a problem. Administration of IV contrast material is not mandatory; however, in a few instances it may facilitate differentiation of perianeurysmal fibrosis from a contained leak. This is because fibrotic tissue demonstrates detectable enhancement, whereas periaortic hematoma does not enhance—unless free extravasation of contrast-enhanced blood from the aortic aneurysm occurs, in which case the diagnosis of rupture is easily made.

CT images should be acquired quickly, because even normotensive patients may suddenly become hemodynamically unstable. In fact, the false sense of security that sometimes develops when stable patients with ruptured aneurysms are being evaluated and prepared for surgery may lead to delays that subsequently adversely affect patient mortality.²⁶⁶ CT images are usually obtained through the abdomen and pelvis with a collimation of 7 to 10 mm. Images should be reconstructed at contiguous 7- to 10-mm intervals.

When seen on CT scans, aneurysm ruptures are often extensive and easy to identify (Fig. 43–13). Acute extraluminal blood shows soft tissue attenuation. It has a vermi-

Figure 43–13. Ruptured abdominal aortic aneurysm. Contrast-enhanced CT scan demonstrates active intravasation of blood into the extensive aneurysm thrombus (black arrow). Blood is also extravasating into the retroperitoneum through a large defect in the anterior wall of the aorta (white arrowhead). Disruption of the aortic calcification can be seen.

form, finger-like appearance as it infiltrates between fascial planes in the retroperitoneum.^{105, 233} Most often, blood accumulates in the perinephric space,^{129, 233} although leaks into other retroperitoneal compartments, the duodenum, psoas muscle, IVC, and even into the peritoneal cavity have been observed.^{68, 75}

Identification of the exact site of aortic rupture is possible only in some cases, when a focal disruption in aortic wall calcification is visualized or when there is an area of indistinctness between the aneurysm and the periaortic hematoma. Fortunately, emergency aortic aneurysm repair is performed in a similar fashion (by initially clamping the aorta near the level of the diaphragm), regardless of the exact site of leak; therefore, its identification is not essential.²³³

Occasionally, areas of rupture may be small and contained, and detection of extraluminal blood may be difficult or even impossible.²³³ These areas may represent subacute, warning (or sentinel) bleeding episodes. These patients are at risk of massive rupture at any time.⁶⁸ Small, contained ruptures can produce a tiny amount of fluid or soft tissue-attenuation material adjacent to the aorta (Fig. 43-14). Slight changes in the distribution of aortic wall calcification, which can be difficult to identify if comparison studies are not available, may be produced by the aortic wall defect. As previously described, the presence of the draped aorta sign (in which the aortic wall is not identified posteriorly and the posterior aspect of the aorta is closely opposed to the vertebral bodies and follows their contour) strongly suggests that a contained leak may be present even when no periaortic fluid or soft tissue is identified.⁹²

In some symptomatic patients, CT may demonstrate only an AAA without a draped aortic contour and with no obvious or subtle evidence of contained or free rupture. Grotorex and colleagues encountered six patients with surgically diagnosed ruptured AAAs; emergency CT examinations performed on these six patients within 24 hours of surgery were interpreted as showing no evidence of rupture.⁸⁴ In only one patient was the scan retrospectively believed to have been erroneously interpreted as negative for rupture. In one symptomatic patient, massive retroperi-

toneal hemorrhage was easily visualized on a subsequent CT scan obtained 28 minutes after the initial scan had revealed no extraluminal blood. The authors therefore suggest that even if an apparently nonruptured aneurysm is present in a patient with abdominal pain and in whom a diagnosis of aneurysm rupture is being considered, hospital admission and close monitoring of the patient are crucial. Emergency surgery may still be strongly considered in these patients regardless of the lack of evidence of aneurysm rupture according to the CT examination.

Alternatively, hemodynamically stable patients with large symptomatic aneurysms but no CT evidence of rupture may be able to undergo semielective aneurysm repair (after 24 to 48 hours of close monitoring). In some series, operative mortality falls drastically (to 17% from between 35% and 50%) when the patient can be prepared and when surgery can be performed in a semielective fashion.²³³

Many patients who are examined by CT to rule out aortic rupture have truly negative CT findings.²³³ Nonetheless, because large aneurysms with no rupture cannot be reliably distinguished from those with small, subacute, contained, or impending ruptures, semielective repair may still be indicated if no other cause of abdominal pain can be identified. Fortunately, sometimes with a CT scan that is negative for rupture, other nonvascular causes of abdominal pain can be identified.

False-positive CT diagnoses of aneurysm rupture can be minimized if the radiologist is aware of certain potential pitfalls. Asymmetrical aneurysm thrombus and volume averaging of periaortic tissue with the aneurysm lumen at the level of the aneurysm neck can lead to the misdiagnosis of small contained ruptures in some instances. Perianeurysmal fibrosis can be confused with periaortic hemorrhage, particularly if scans are performed without IV contrast material (Fig. 43-15). As previously noted, if the duodenum is not opacified with oral contrast material, the third and fourth portions can sometimes be confused with periaortic hemor-

Figure 43-14. Ruptured abdominal aortic aneurysm. A small "contained" rupture is visualized along the left posterolateral aspect of this aneurysm on this contrast-enhanced CT image.

Figure 43-15. Perianeurysmal fibrosis mimicking aortic rupture. Poorly defined soft tissue attenuation material surrounds the right lateral aspect of the abdominal aorta (arrows) on an unenhanced CT scan. The patient had presented with acute severe back pain. The periaortic soft tissue was suspected to represent a small contained aneurysm rupture. At emergency surgery, only retroperitoneal fibrosis was found.

Figure 43-16. Enlarged lymph nodes (N) mimicking retroperitoneal hemorrhage in a patient with an abdominal aortic aneurysm (A) and metastatic prostate cancer. Nondynamically enhanced scan shows rounded and well-defined retroperitoneal nodes. The patient had presented with back pain.

rhage. Rarely, retroperitoneal lymphadenopathy can be mistaken for blood (Fig. 43-16).

Aortic ruptures have been rarely encountered in the absence of aneurysmal dilatation. These have been reported after blunt abdominal injury and as a result of nonaneurysmal bacterial aortitis.^{155, 233} The latter diagnosis should, in fact, be considered in a patient who has a fever, positive blood cultures, atherosclerotic changes in the abdominal aorta, and periaortic soft tissue identified on CT or MRI.⁴⁵

Once in a while, a large retroperitoneal hemorrhage develops in a patient who happens to have a large AAA (Fig. 43-17). Usually, the lack of relationship between the hematoma and the aneurysm can be delineated. The fat planes between the aorta and the surrounding hematoma are preserved. No disruption in aneurysm wall calcification is seen, and the aortic wall is not indistinct.

Figure 43-17. Retroperitoneal hematoma in a patient with a small abdominal aortic aneurysm. Unenhanced CT scan shows that the hematoma is separated from the aneurysm by uninfiltated fat. The patient, who had received anticoagulation therapy, experienced sudden flank pain soon after cardiac catheterization.

Other causes of retroperitoneal hemorrhage include blood dyscrasias, vasculitides, and renal infections.^{43, 175} Nonspontaneous causes have included trauma, translumbar aortography, and renal biopsy.⁴³

Aortic Dissection

Aortic dissections are relatively rare, accounting for only 1 in 10,000 hospital admissions.¹⁰³ Mortality rates of untreated dissections are extremely high, approaching 25% at 24 hours, 50% at 1 week, and 75% at 1 month.⁶ Generally, a dissection involving only the descending aorta (DeBakey type III or Stanford type B) is treated with antihypertensive medication. If the ascending aorta is involved (DeBakey types I and II or Stanford type A), surgery (repair of the proximal extent or origin of the dissection) is required; however, exceptions occur. If flow to abdominal visceral organs or the extremities is compromised, emergency angiography may be warranted, during which time additional communications (fenestrations) between true and false lumina may be created or endovascular stents may be inserted.

When dissections involve the abdominal aorta, they almost always have originated in the thorax. An aortic dissection originating in the abdominal aorta is exceedingly rare and is usually produced iatrogenically (e.g., retrograde intimal tears produced by arteriographic catheters, guide wires, or intra-aortic balloon bumps) or develops as a result of blunt trauma.²⁰³

CT is extremely sensitive in depicting the intimal flap and the true and false lumina in both the chest and the abdomen of patients with an aortic dissection (Fig. 43-18). Today CT angiography is performed, clearly mandating that the patient receive a rapid bolus of IV contrast material. After the ascending aorta is evaluated, more scans are obtained farther into the abdomen to assess the inferior extent of the dissection and to determine whether the dissection is extending into the major aortic branch vessels. The intimal flap may extend into any of the major branch

Figure 43-18. Aortic dissection. CT enhanced scan shows an aortic dissection in the midabdomen. The scan easily demonstrates the intimal flap between the anterior true lumen and the posterior false lumen.

Figure 43-19. Aortic dissection. *A*, Contrast-enhanced CT scan reveals extension of an intimal flap from a type III dissection into the left renal artery; the true (arrowhead) and false (arrow) lumina are easily identified. The renal artery involvement resulted in left renal hypoperfusion. Endovascular stent insertion was required to restore renal artery blood flow. *B*, The extension of the false lumen into the left renal artery is well seen on a coronal reformatted image. A small projection from the true lumen into the false lumen (arrow) may represent a penetrating atherosclerotic ulcer.

vessels (Fig. 43-19). Indeed, it is important to identify which major visceral artery branches communicate with which (true or false) lumina. Compromised blood flow in a branch vessel may necessitate emergency therapy.

Although MRI is sensitive in detecting aortic dissections, it is reserved primarily for problematic situations (e.g., when the CT arteriographic results are equivocal or when the patient cannot tolerate iodinated radiographic contrast media because of allergy or renal failure) (Fig. 43-20).⁵ Differences in flow rate, and hence in signal intensity, between true and false lumina may facilitate correct MRI identification of a dissection, but they may also cause confusion. Slow-flowing blood can be mistaken for hematoma. Additionally, severely ill patients (and patients with suspected aortic dissections are often acutely

ill) are more difficult to manage and observe in most MRI suites than in most CT rooms.

Occasionally, the false lumen of an aortic dissection is completely thrombosed when first detected. Distinguishing an AAA from a chronic dissection containing a clotted false lumen may not be extremely difficult by CT or MRI.²⁷³ The thrombus may have a similar appearance in both instances.

Heiberg and coworkers compared CT scans of 36 patients with aneurysms to scans of 24 patients with dissections.⁹⁹ Linear peripheral calcifications were more common in patients with aneurysms (70%) than in patients with dissections (20%), although neither the appearance nor the location of the aortic calcification was completely specific. Increased density of a thickened aortic wall on precontrast scans was seen in only one patient with an aneurysm but in 44% of patients with dissections. The residual lumen was round in 94% of patients with aneurysms but in only 29% of those with dissections. Differences in wall thickness or aortic size could not be demonstrated. The authors concluded that in some instances these features might be used to predict whether an aortic thrombus resides within a completely thrombosed dissection or within a thoracoabdominal aortic aneurysm.

Not surprisingly, medically treated aortic dissections may evolve with time. Yamaguchi and colleagues demonstrated that serial CT studies showed changes in false lumen size or the degree of thrombus in 7 of 13 patients with DeBakey type III dissections.²⁷³ In each of their three patients whose false lumina were completely thrombosed initially, the false lumen disappeared or shrank by 1 to 2 months after the first scan. These authors concluded that CT might be used to monitor patients with medically treated dissections. Thus, serial CT or MRI examinations may prove helpful when a dissection is suspected and treated but the initial CT appearance is not diagnostic.

Figure 43-20. Aortic dissection. Limited flip-angle MR image demonstrates the intimal flap (arrows) between the bright signal in the true and false lumina.

Penetrating Atherosclerotic Ulcers

Penetrating atherosclerotic ulcers of the aorta may lead to hemorrhage in the wall of the aorta and intimal displacement away from the media.¹²³ This leads to the creation of a false aortic lumen. Although penetrating ulcers, conceivably, may develop anywhere along the course of the aorta, they have almost always been identified in the descending thoracic aorta.

To our knowledge, only one case of a penetrating ulcer developing in the infrarenal abdominal aorta has been reported, and it resulted in development of an intramural hematoma.¹⁷⁷ When penetrating ulcers are present, the ulcers are frequently visualized on CT scans as focal irregular outpouchings extending off the aortic lumen (see Fig. 43-19B).

Treatment is controversial. Although a conservative (nonsurgical) approach has been effective in some hemodynamically stable patients, some authors recommend that all patients with penetrating ulcers be treated surgically.¹⁷⁷

Small Aorta

In rare instances, the caliber of the aorta may actually be smaller than normal. This situation is commonly a result of either atherosclerotic aortic occlusive disease (with extensive atherosclerotic aortic calcification usually present) or severe hypotension (which is always clinically obvious) (Fig. 43-21).

Treatment of Abdominal Aortic Aneurysms

The preferred surgical treatment of AAAs is an end-to-end anastomosis with endoaneurysmorrhaphy. The proximal and distal ends of the graft are attached to uninvolved portions of the aorta, iliac, or femoral arteries in an end-to-end manner after incision and partial resection of the

anterior wall of the aneurysm. The remaining aneurysm sac is then wrapped loosely around the graft and sutured closed.

This approach is recommended because blood flow patterns are physiologic (in contrast to end-to-side proximal anastomoses). In addition, the endoaneurysmorrhaphy is thought to lessen the incidence of injury to the vena cava, iliac veins, and lumbar vessels. Postoperatively, persistence of the aneurysmal shell around the graft provides an additional protective layer between the graft and the overlying duodenum, decreasing the frequency of postoperative aortoenteric fistulas.

Although endovascular stent-graft insertion is usually reserved for patients who are poor operative candidates, at some institutions this much less invasive alternative is now being performed as an alternative to elective aneurysm repair.¹⁵⁹ Preliminary studies have demonstrated that the mortality and long-term survival rates are similar for patients receiving standard operative grafts and for those receiving endovascular grafts; however, the expenditure of hospital resources (blood transfusions, time spent in the operating room or the intensive care unit, and time spent in the hospital) is much lower for patients treated with endovascular grafts.¹⁷³ It must be emphasized, however, that vascular surgeons must be available to perform emergency aneurysm repairs in any patient undergoing stent-graft insertion, since catastrophic complications such as aortic rupture, although very rare, may occur during the procedure.¹⁷⁸

Endovascular stent-graft insertion appears to represent an excellent alternative to open surgical aortic aneurysm repair in some patients, but whether this procedure will ultimately replace surgery is not yet clear. The significance of the relatively common short-term complication of stent-graft leakage is not yet known, although some vascular radiologists now perform selective arterial embolization at the time of graft insertion in an attempt to reduce its incidence. Also, long-term morbidity has not yet been assessed.

Evaluation of the Post-treatment Abdominal Aorta

After Aortic Aneurysm Repair

CT is the imaging study of choice for evaluation of patients with suspected complications of aortic graft repair.²³³ Several authors have recommended that CT also be performed for follow-up of patients long after aortic graft insertion even when no complications are clinically suspected.¹²² This is because up to 14% of patients may develop additional areas of aneurysmal dilatation, either at the graft anastomoses or elsewhere. A significant minority of these complications may be significant, and additional treatment is required.

CT evaluation of these patients is best performed through the abdomen and pelvis at contiguous 7- to 10-mm intervals after dynamic bolus IV contrast enhancement. Although CT angiography is necessary for preoperative aortic aneurysm imaging, it is not necessary here. Visualization of the aortic branch vessels in great detail is not required. Use of IV contrast material is essential, however,

Figure 43-21. A small aorta and a slitlike inferior vena cava are noted on this contrast-enhanced CT scan. This pediatric patient was severely hypotensive. The right renal laceration, enhancing bowel, and hemoperitoneum can be seen.

because it facilitates the distinction between anastomotic aneurysms and other perigraft fluid collections (e.g., hematomas, abscesses, seromas). In general, scans should be obtained after oral contrast material has been administered.

Although additional CT image acquisition prior to administration of oral contrast material has occasionally aided the detection of extravasation of contrast-enhanced blood from the graft into bowel in some patients with aortoenteric fistulas, usually no such extravasation can be identified even when these fistulas are present. Further, indirect signs of a fistula are almost always easily identified.

During CT or MRI evaluation after open aortic aneurysm repair, it is important to determine the presence of any perigraft fluid or air or aneurysm formation at the graft anastomoses. Normal aortic aneurysm grafts with endoaneurysmorrhaphy may have a CT or an MRI appearance strikingly similar to that of unrepaired aortic aneurysms. Initially, a thrombus in the wraparound aneurysmal sac may look like a thrombus around a centrally opacified blood-containing lumen in an aneurysm.

Subtle differences often exist. The lumen of the aortic graft is usually smooth and circular; however, the lumen of an aneurysm is commonly at least slightly irregular. The graft itself may have relatively high attenuation on CT and thus may be identifiable on precontrast scans (Fig. 43-22); after contrast enhancement, however, this distinctive feature is usually not apparent. On immediate postoperative scans, it is not unusual to see some perigraft fluid or air

(Figs. 43-23 and 43-24). With time, the space between the aneurysm wrap and the graft should diminish. Usually, all perigraft air has disappeared by 3 weeks and all perigraft fluid by 3 months. Only a minimal amount of perigraft soft tissue, most likely corresponding to perigraft fibrosis, should be visible after several months have passed.

After Endovascular Stent-Graft Insertion

Helical CT or MRI is recommended for imaging patients after endovascular stent-graft insertion. In these patients, CT or MR arteriography may be helpful. Thus, in this instance, thinly collimated images should be obtained and images reconstructed at contiguous or overlapping intervals. Oral contrast material should not be administered to any patient in whom 3D reconstructions are to be created because it will produce artifacts and limit the utility of the reconstructed images. Although a number of studies have demonstrated that arterial phase images are the most sensitive for detecting stent-graft leaks,⁸⁰ biphasic scanning (during which time both arterial and portal venous phase images are obtained) has been found to be most accurate in one series.⁷⁷

Endovascular stent-grafts are usually easily identified on CT scans because of their metallic components (Fig. 43-25).⁷⁸ On MR images, the metallic graft is not specifically seen and many stents may create susceptibility artifacts.

Several important observations should be made on CT

Figure 43-22. End-to-side aortoiliac bifurcation graft. *A*, The proximal end of the graft is visualized just anterior to the heavily calcified native distal abdominal aorta on a contrast-enhanced CT scan. *B*, The iliac limbs (arrows) are located anterior and slightly medial to the native iliac arteries. *C*, The femoral portions of the Y graft are easily identified anterior to the native femoral vessels, just cephalad to the distal anastomosis (arrows). On these delayed enhanced scans, the graft has a higher attenuation than that of the flowing blood within it.

Figure 43-23. Endoaneurysmorrhaphy shortly after aortic aneurysm repair. Unenhanced CT scan demonstrates the partially calcified wall of the native aorta surrounding thrombus or perigraft fluid, which in turn surrounds the aortic graft. On this scan, the aortic graft is of higher attenuation than that of the blood in the aortic lumen. Extensive persistent hematoma from a recent aneurysm rupture in the retroperitoneum can be seen on the left.

scans or MR images obtained in patients after stent-graft insertion:

1. The widest diameter of the AAA should be measured because reduction in aneurysm diameter is considered to be the best indicator of adequate aneurysm exclusion by the graft.⁷⁸ Indeed, an increased aneurysm diameter should be viewed with concern, since an endograft leak may be present even when the CT scan does not demonstrate it directly.²⁵⁵
2. The diameters of the proximal and distal aneurysm necks should be measured because they may increase after stent insertion.⁷⁸

Figure 43-24. Endoaneurysmorrhaphy shortly after aortic aneurysm repair. Gradient-echo MR image reveals the high signal intensity of flowing blood within the aortic graft, but the blood and fluid between the graft and the native aorta (arrows) demonstrate low signal intensity. Normally, within about 3 months of surgery, most of the fluid between the graft and the aneurysm wrap is resorbed.

3. The images should be scrutinized for evidence of perigraft leaks (see later).
4. The patency of the inferior mesenteric and lumbar arteries should be assessed because these vessels, if patent, can serve as the source of perigraft leaks (resulting from retrograde filling of the aneurysm).
5. The configuration of the graft should be assessed. Graft deformation, angulation, or change in caliber can lead to migration.
6. The patency of the graft should be determined to ensure that thrombosis has not developed.⁷⁸

Complications of Abdominal Aortic Aneurysm Treatment

Complications of conventional abdominal aortic graft surgery include the following:

- Graft infections (1% to 6%)²⁰³
- Aortoenteric fistulas (1% to 5%)
- Anastomotic aneurysms (up to 5%)
- Graft leak or rupture²³³

Surgical repair, usually with graft resection, is indicated in any patient in whom intra-abdominal and deep pelvic extension of graft infection, an aortoenteric fistula, or large or symptomatic pseudoaneurysm formation is identified.

Complications of endovascular stent-graft insertion may include leaks (20% to 47% of patients).^{18, 77, 78, 81, 159, 160, 173} In one series, for example, leaks were detected in 13 of 50 patients 1 week (12 patients) or 3 months (1 patient) after stent-graft insertion.⁷⁷ Stent-graft occlusions and migrations may also be encountered.

Graft Infections

Aortic graft infections are potentially catastrophic early complications of aortic bypass surgery.²⁴⁶ In most patients, groin infections develop initially at the distal anastomoses of aortobifemoral bypass grafts. In these instances, the diagnosis is obvious. If the groin infection remains undetected until 6 weeks or more after surgery, usually it has spread into the pelvis and sometimes the retroperitoneum.

Graft infection with extension into the pelvis or retroperitoneum often results in the formation of fluid collections and/or air in the vicinity of the aortic graft; both fluid collections and air are easily visualized on CT scans. The fluid collections are often irregular and septate.⁸⁸ Perigraft fluid and hematomas may be confused with abscesses in the immediate postoperative period (within 6 weeks of surgery), since air and fluid are normally visible in the operative bed.¹⁹⁰ Follow-up CT scans can be obtained when infection is considered likely in patients in whom retroperitoneal air visualized by CT may be secondary to recent surgery. Pathologic gas collections (often posterior and multilocular in relation to the graft) increase in size over time, whereas postsurgical collections of air (usually unilocular and anterior) should diminish.¹⁹⁰ Indium-labeled white blood cell scans may prove useful in some instances (Fig. 43-26). Ultimately, CT-guided needle aspiration may be necessary for a definitive diagnosis.²³³

CT diagnosis of graft infection in patients who are not

Figure 43-25. Endovascular stent-graft. *A*, Contrast-enhanced CT scan demonstrates a well-positioned, patent, infrarenal endovascular stent-graft in the midabdominal aorta of an 83-year-old man. *B*, A more caudal image demonstrates bilateral common iliac components. *C*, The graft is also well visualized on a volume-rendered 3D reconstruction.

in the immediate postoperative period (>3 months after surgery) is not nearly as difficult.⁶⁴ Any perigraft soft tissue, fluid, or air in these patients almost always suggests infection (Fig. 43-27).¹⁹⁰

Treatment of graft infections varies, depending on the extent of the infection. A localized groin infection can occasionally be treated conservatively with antibiotics; however, once intra-abdominal spread occurs, most vascular surgeons recommend complete graft removal with extra-anatomic bypass.²³⁰ Some researchers have successfully performed in situ graft replacement in these patients (after débridement and antibiotic irrigation of the graft bed), although the reinfection rate is still relatively high at over 20%.²⁷⁷ Partial graft excision is considered to be a suboptimal treatment, resulting in the need for additional surgical procedures in as many as 60% of patients.¹⁹

Some radiologists have advocated the use of percutane-

ous techniques as a precursor to surgery or for definitive treatment of infected grafts in patients who are not good operative candidates.²²² Belair and colleagues treated 11 patients with percutaneous drainage of infected perigraft fluid collections.²⁰ Sepsis resolved in nine patients, four of whom were treated with percutaneous drainage and antibiotics alone. Graft resection followed percutaneous drainage in the remaining five patients. Perioperative mortality and complication rates were actually lower in the patients whose surgery was preceded by percutaneous treatment than in patients who proceeded directly to surgery.

Aortoenteric Fistulas

Aortoenteric fistulas result from the persistent pulsatile pressure of the proximal graft anastomosis on the duodenum or from a low-grade infection that disrupts the suture

Figure 43-26. Infected aortic graft. *A*, Unenhanced CT scan shows fluid-attenuation material (arrow) surrounding the left iliac limb of an aortobifemoral Y graft. In this case, the infection is not caused by a gas-producing organism. *B*, Anterior view from an indium-labeled leukocyte scan demonstrates increased uptake in the left external iliac region (arrow) corresponding to the infected aortobifemoral graft.

line. Usually, these fistulas do not develop until many months after surgery. In one series, aortoenteric fistulas were not encountered until a mean of 32 months after surgery (range, 8 to 52 months).¹⁷ The fistulas usually develop between the aortic graft and adjacent duodenum, although communication with the jejunum, ileum, and colon has also been observed.²³³

The main clinical manifestation is gastrointestinal (GI) tract bleeding; however, bleeding may be occult in some patients. If bleeding remains untreated, however, life-threatening hemorrhage eventually develops in all patients.¹⁷

CT is able to detect aortoenteric fistulas, usually by showing indirect signs of their presence (i.e., extraluminal air and adjacent bowel wall thickening) (Fig. 43-28). Extravasation of high-attenuation, contrast-enhanced blood from the aorta into the duodenum can be seen only in a

patient given IV, but not oral, contrast material (Fig. 43-29). Even when this technique is employed, visualization of such extravasation is extremely rare in a patient stable enough to undergo CT (probably because bleeding is either intermittent or very slow in most patients referred for CT). For this reason, CT examinations are usually performed after administration of oral and IV contrast material.

On many occasions, patients with aortoenteric fistulas may have perigraft fluid and soft tissue and extraluminal air but no identifiable bowel wall thickening. In these instances, a specific diagnosis cannot be made and differentiation from aortic graft infection is not possible.¹⁵¹ Because treatment of aortoenteric fistulas and treatment of infected grafts are similar (usually consisting of graft resection), the inability to distinguish between these two complications is not crucial. Although extra-anatomic bypass is often performed if evidence of overt infection is seen, in situ replacement of the graft is now commonly performed.^{17, 233}

Figure 43-27. Infected aortic graft. Air has accumulated within the space between the graft and the surrounding native aorta on this unenhanced CT scan. The patient had undergone endoneurorrhaphy.

Anastomotic Aneurysms

Anastomotic aneurysms occur most frequently in the femoral area and usually are identified well after surgery. In one series, they were detected an average of 6.2 years after aortic aneurysm repair.⁵⁰ The incidence of anastomotic aneurysms is estimated to be 0.8% at 5 years, 6.2% at 10 years, and 36% at 15 years.^{165, 176} These aneurysms may originate either from pseudoaneurysm formation, as a result of breakdown of the suture line, or from true aneurysm formation, secondary to progression of atherosclerotic disease proximal or distal to one of the anastomoses. In one series, for example, 7 of 10 anastomotic aneurysms were pseudoaneurysms and the remaining 3 were true aneurysms.¹⁷⁶

Dynamically enhanced CT can often be used to facilitate a specific diagnosis by its ability to identify a mass or collection contiguous with the aorta or iliac or femoral vessels at the level of one of the anastomoses in which

Figure 43-28. Aortoenteric fistula. *A*, Unenhanced CT scan shows a small amount of air, identified between the aortic graft and the adjacent duodenum. Distinction cannot be made between aortoenteric fistula and graft infection on the basis of this image. *B*, A slightly more cephalic scan (same patient) reveals mild thickening of the third portion of the duodenum. This finding, coupled with a history of gastrointestinal tract bleeding, suggested the correct diagnosis.

contrast-enhanced flowing blood can be visualized (Fig. 43-30). On unenhanced CT scans, however, anastomotic aneurysms must be distinguished from other perigraft masses and collections (e.g., hematomas, abscesses, lymphoceles). Such a distinction is crucial, particularly if percutaneous aspiration is considered in a patient with a suspected graft infection (because aspiration of a pseudoaneurysm is not desirable).

Treatment of large (>2 cm in maximal diameter) or symptomatic aneurysms consists of resection. Small, asymptomatic aneurysms can be followed.

Graft Rupture

Rupture of a prosthetic graft is an uncommon late complication, usually occurring 8 to 20 years after its placement.²³⁶ Presentation may be acute (with ischemia, pain, or shock), or indolent (with rest pain or a groin mass). The cause of graft rupture may be rupture of an anastomotic pseudoaneurysm or a defect in the graft, possibly from fabric deterioration. Graft degeneration more commonly

involves the distal branches in a Y graft but may also involve the main aortic segment.

Treatment depends on the site of graft deterioration. If distal deterioration has occurred, resection of the graft defect is performed. If the proximal portion of the graft has deteriorated, the graft is replaced. CT usually demonstrates either a pseudoaneurysm or dilatation of the graft.²³³

Endovascular Stent-Graft Leaks

It is not yet clear whether the fairly common development of graft leaks will have a significant adverse effect on long-term prognosis after endovascular stent-graft insertion. There are several types of endovascular stent-graft leaks¹⁸:

Type I (perigraft leak): A leak may develop at the proximal or distal insertion site. This leak may develop immediately or may occur over time as the relationship of the endovascular graft to the aorta changes, since the aortic diameter and orientation is expected to change as a response to graft insertion and aneurysm exclusion.

Figure 43-29. Aortoenteric fistula. This patient was studied before oral (but after intravenous) administration of contrast medium. *A*, Contrast-enhanced blood extends from the aorta (in a pseudoaneurysm) toward bowel in the left upper quadrant. *B*, A more cephalic scan demonstrates contrast-enhanced blood in the proximal jejunum (arrow), confirming the diagnosis of aortoenteric fistula.

Figure 43-30. Anastomotic aneurysm in an 84-year-old woman who had undergone aortic aneurysm repair years earlier. CT scan demonstrates a large mass in the left periaortic region at the level of the proximal anastomosis (arrows). Contrast-enhanced flowing blood can be identified in the center of this anastomotic aneurysm.

Type II (endoleak): A leak may also occur as a result of retrograde flow into the aneurysm sac from patent aortic branch vessels, most commonly via the inferior mesenteric or lumbar artery.

Types III and IV: Less commonly, a graft leak may be caused by graft fabric tears, disintegration, or flow through the graft itself as a result of the porous graft wall.

At present, many persistent leaks are treated aggressively, often by angiographic embolization, because it is believed that these leaks predispose patients to aortic rupture, much as did the original untreated aneurysm.^{17, 18} Some suggest, however, that leaks developing through retrograde flow through aortic branch vessels can be treated conservatively (i.e., merely followed with sequential CT examinations), provided that the diameter of the aneurysm sac decreases over time, since these are least likely to eventually lead to rupture.¹¹² Leaks at the proximal ends of the stent-grafts are thought to be at greatest risk of rupture.⁷⁸

Endograft leaks are often identified on CT or MRI as focal collections of contrast-enhanced blood external to the graft. These collections may or may not be within the aneurysm (Fig. 43-31). Some have suggested that endograft leaks should be suspected if the CT or MRI examination demonstrates an increase in the diameter of the excluded aneurysm, even when the leak itself is not visualized.¹¹² In one report, aneurysm rupture developed 16 months after stent-graft insertion.²⁵⁵ The patient had undergone two CT scans, the first immediately after stent-graft insertion and the second 7 months later. Neither scan demonstrated a leak; however, the aneurysm size had increased on a follow-up scan.

Helical CT is thought to be superior to MRI in detecting endograft leaks because the endograft can be visualized directly on CT scans, whereas it appears merely as an area of signal void on MR images. Despite the perceived advantages of CT, MRI can certainly be used to detect endograft leaks as well, and both are considered superior

Figure 43-31. Endovascular stent-graft with leak. *A*, Digital radiograph obtained at the time of insertion demonstrates a long endovascular stent-graft extending from the abdominal aorta into both common iliac arteries. *B*, Gadolinium-enhanced, T1-weighted MR image reveals a focal collection of high signal intensity external to the stent but within the aneurysmally dilated aorta (arrow); this indicates a leak. On other images, this leak was noted to be contiguous with a lumbar artery, indicating that it was caused by retrograde flow from this vessel. The signal void created by the graft can be seen.

to aortography. In one series, helical CT identified leaks in 13 patients with endografts.⁷⁷ In contrast, aortography identified the leak in only 8 of these 13 patients. Selective or superselective injections were required for angiographic identification of leakage in the remaining five patients.

CT and MRI may also be used to detect the cause of an identified endograft leak, thereby facilitating treatment planning. Leaks that lie outside the aortic aneurysm (perigraft leaks) are usually caused by mechanical problems related to graft insertion or to the changing orientation of the graft with the aneurysm. Intra-aneurysmal leaks that are separate from the prosthesis and anterior are probably the result of retrograde flow from the inferior mesenteric artery.⁷⁷ Intra-aneurysmal leaks that are posterior and lateral and that have a base with the aneurysm margin are probably caused by retrograde flow through the median sacral or lumbar arteries (see Fig. 43–31).

Endovascular Stent-Graft Migration and Other Complications

Other long-term complications of endovascular stent-graft insertion include:

- Thrombosis (reported in 0% to 15% of patients)
- Peripheral embolization distal to the graft
- Migration
- Disconnection of components of modular or multiple grafts^{95, 253}

Stent-graft migration can produce additional complications. In one report, migration and kinking of a stent-graft resulted in formation of an aortoenteric fistula 20 months after insertion.⁹⁵ Thrombosis of the graft and change in graft position or morphology can easily be detected by CT (Fig. 43–32).

Veins

Normal Anatomy

The IVC is formed by the confluence of the two common iliac veins, usually at the level of the fourth or fifth lumbar vertebral bodies, just caudad to the aortic bifurcation. The IVC courses to the right of the aorta, becoming slightly more ventral in location just before it traverses the diaphragm.¹²⁸

The IVC is formed by the development and partial regression of the three paired venous systems in the embryo: the postcardinal veins, the subcardinal veins, and the supracardinal veins. Normally, the right supracardinal vein becomes the infrarenal portion of the IVC, the subcardinal vein and its anastomoses become the perirenal and suprarenal portion of the inferior vena, and the confluence of the hepatic veins forms the intrahepatic portion of the IVC. The upper portions of the right and left supracardinal veins form the azygous and hemizygous systems.⁴⁷ The normal IVC is easily identified on essentially all CT and MRI examinations.

The gonadal veins are located just lateral to the ureter and anterior to the psoas muscles in the lower abdomen. They ascend parallel to and cross anteriorly over the ureters (about half-way between the IVC bifurcation and the level

Figure 43–32. Endovascular stent-graft with thrombosis of a limb. Intravenous contrast-enhanced CT scan in a 68-year-old man who had undergone insertion of an endovascular stent-graft (2 months earlier) reveals contrast-enhanced blood flowing through the left common iliac limb but no enhancement in the right common iliac limb. The right limb is completely thrombosed. The aortic aneurysm surrounding the graft is also completely thrombosed but is still quite large, probably because the thrombus there has not had time to be resorbed.

of the renal hila) and then continue cephalad just medially to the ureters, usually emptying into the left renal vein (left gonadal vein) or the IVC (right gonadal vein). Despite their relatively small size in many patients, the gonadal veins are commonly visualized. On occasion, they may appear prominent in patients with no identifiable pathologic cause of dilatation (Fig. 43–33). This prominence, therefore, is probably a normal variant.

Venous Abnormalities

A variety of abnormalities of the retroperitoneal veins can be encountered, including a number of IVC venous

Figure 43–33. Prominent gonadal veins (arrows) are visualized on this dynamically enhanced CT scan. They should not be confused with enlarged retroperitoneal lymph nodes.

congenital anomalies. A thrombus may form in the IVC and gonadal veins, either because of spread of more distally located thrombi or as a result of a neoplasm. The retroperitoneal veins may become dilated, providing a pathway for collateral blood flow. On rare occasions, air can be identified in the IVC.

Cross-sectional imaging is now performed occasionally to assist interventional radiologists in planning treatment of venous thrombosis. By showing the extent of the thrombus, these studies can assist the interventionist in planning for insertion of the IVC filter.

In the text that follows, the common venous anomalies and abnormalities of the IVC and gonadal veins are detailed. CT evaluation of patients before and after placement of the IVC filter is reviewed next.

CT and MRI Technique

Retroperitoneal venous abnormalities are usually detected on CT studies performed to evaluate other structures. For this reason, CT scans are often obtained with relatively wide image collimation (of 7 to 10 mm) and relatively large reconstruction intervals (of 7 to 10 mm). When detailed evaluation of the retroperitoneal veins is required, however, it is prudent to obtain contiguous or even overlapping reconstructions of more thinly collimated images; these scans should be obtained following dynamic IV injection of contrast material.

In most instances, a rapid bolus of contrast material can help differentiate a blood vessel from a lymph node. Both the ability to follow a rounded structure on sequential images (indicating the vessel's tubular shape) and the higher attenuation of enhanced and flowing blood within the vessel lumen are helpful in making this distinction. Helical CT scanning is most efficient. If 3D reconstructions are to be created, image collimation should be 2.5 to 3 mm, with images reconstructed at 1.25-mm intervals.

Because of its capability to distinguish blood vessels from other retroperitoneal structures, MRI is preferred over CT when retroperitoneal venous imaging is specifically desired. Coronal and sagittal images are also easily obtained. Both "black-blood" (T1-weighted and T2-weighted spin-echo) and "bright-blood" (gradient-echo and 2D and 3D time-of-flight) imaging sequences can be employed. In particular, gradient-echo images in both the axial and the sagittal plane are rapid sequences that can provide good evaluation of anatomy and can facilitate assessment of veins for intraluminal thrombi. MRI contrast agents (e.g., gadolinium) produce brisk venous enhancement. When this approach is coupled with use of 3D reconstruction techniques (e.g., maximum intensity projection), excellent images of the retroperitoneal veins can be obtained.

Venous Anomalies

Failure of normal embryologic development may result in many possible venous anomalies, but only a small number have actually been reported. Recognition of these variants with CT and MRI prevents them from being confused with other abnormalities. Furthermore, knowledge of these

anomalies is helpful before surgery, particularly in patients undergoing a shunt procedure for portal hypertension, kidney donation, AAA repair, or nephrectomy. In one series, for example, it was found that 40% of retroaortic left renal veins had been injured in a large group of patients undergoing abdominal aortic surgery.²⁷

Circumaortic Left Renal Vein

Circumaortic left renal veins are thought to result from partial persistence of the posteriorly located left supracardinal vein and a midline left-to-right supracardinal anastomosis. In one series of 433 patients undergoing CT examinations, 4.4% were found to have this condition.²¹⁷

When a circumaortic vein is present, the ventral portion of the left renal vein is usually normal in location. This component drains the inferior and ventral portions of the left kidney and traverses anterior to the abdominal aorta before inserting into the IVC. After draining the kidney, the dorsal vein, which drains the superior and dorsal aspects of the left kidney, continues posterior to the abdominal aorta and usually inserts several centimeters more caudad into an area of saclike dilatation of the IVC.²⁵²

The ventral vein is always equal in size to or larger than the dorsal vein.²¹⁷ Both ventral and dorsal components of circumaortic left renal veins are commonly identified with CT and MRI. The presence of the retroaortic component is suggested, however, even when it is not directly seen, if a medially located triangular diverticulum off the IVC is identified at or below the level of the ventral left renal vein.¹³² The detection of a circumaortic left renal vein is usually an incidental observation. As previously noted, this usually does not affect patient care unless surgery is anticipated.

Retroaortic Left Renal Vein

A retroaortic left renal vein forms when the ventral component of a circumaortic renal vein has involuted. This anomaly is less common than a circumaortic left renal vein, having been reported in 1% to 3.3% of patients.^{217, 252} In the previously cited review of 433 CT examinations, retroaortic renal veins were detected by CT in 1.8% of patients.²¹⁷ Cross-sectional imaging findings are notable for absence of the ventral left renal vein (Fig. 43-34). The dorsally located renal vein is often visualized just caudad to the level of the renal hila.

Transposition of the Inferior Vena Cava (Left-Sided Inferior Vena Cava)

A left-sided IVC, resulting from persistence of the infrarenal left supracardinal vein and regression of the right supracardinal vein, occurs in 0.2% to 0.5% of the population.¹⁶¹ It appears as a round, tubular structure to the left of the aorta that extends superiorly to the left renal vein. The suprarenal portion of the IVC continues cephalad in its normal right-sided location because the subcardinal portion of the IVC is not involved.¹²⁸

Duplication of the Inferior Vena Cava

Duplication of the IVC, occurring with an incidence of 0.2% to 3%, results from the persistence of both the infrare-

Figure 43-34. Retroaortic left renal vein in a patient with splenomegaly, as seen on a dynamically enhanced CT scan.

nal right and the infrarenal left supracardinal veins.^{115, 161, 254} Usually, the left-sided IVC drains into the right by emptying into the left renal vein. Only a right-sided IVC is seen cephalad to this level (since subcardinal development is again normal) (Figs. 43-35 and 43-36). It is not uncommon for one of the vessels to be dominant. Bolus CT examination may not result in simultaneous or equal enhancement of both the right and the left portions of the IVC because contrast media may flow preferentially into the dominant vessel.¹¹⁵

Periureteric Venous Ring, Circumcaval or Retrocaval Ureter

Occasionally, an abnormally positioned IVC or a periureteric venous ring at the level of the third or fourth lumbar vertebral body medially displaces the right ureter. This abnormality, termed the *circumcaval ureter*, or *retrocaval ureter*, occurs with a frequency of 0.9 per 1000 patients.¹⁸⁸ Most patients have a single right preureteric IVC, which is thought to represent persistence of the right posterior cardinal vein with failure of development of the infrarenal right supracardinal vein.^{188, 226}

Symptoms (secondary to obstruction), when present, usually appear late. CT and MRI can be used to identify a circumcaval ureter if the right ureter partially encircles the inferior cava, passing first posteriorly and then medially to the IVC (Fig. 43-37).¹³⁶ Lateral positioning of the upper abdominal IVC in relation to the right ureter without an identifiable retrocaval component of the ureter, although seen in all patients with circumcaval ureters, is usually a normal variant (visualized in 6% of the general population).¹³⁶

Azygous Continuation of the Inferior Vena Cava

Azygous continuation of the IVC results both from failure of the hepatic and right subcardinal veins to merge and from persistence of a suprarenal right subcardinal-to-right supracardinal anastomosis, allowing venous drainage to continue up the azygos vein to the superior vena cava.⁴²

Figure 43-35. Duplicated inferior vena cava, seen on intravenous, nondynamically contrast-enhanced CT scans. *A*, Caudally, both right and left inferior venae cavae are noted on either side of the aorta. *B*, The left inferior vena cava joins the left renal vein, which then crosses over to join the right inferior vena cava. *C*, Above the renal hila, only a single right inferior vena cava is present.

Figure 43-36. Duplicated inferior vena cava. *A*, Coronal T1-weighted, spin-echo MR image shows portions of both the right and left inferior venae cavae (arrows). The left inferior vena cava is located entirely caudad relative to the level of the left renal vein. *B*, MR image in a more anterior location demonstrates the enlarged left renal vein (into which the left inferior vena cava has emptied) (arrow) crossing the midline to drain into the right inferior vena cava.

Figure 43-37. Circumcaval ureter. *A*, CT scan demonstrates the proximal portion of the right ureter (arrow) posterior to the inferior vena cava as it courses medially from the ureteropelvic junction. *B*, On a slightly more caudal image, the ureter (arrow) is located quite medially before continuing inferiorly in its more normal lateral position.

This anomaly is observed only rarely. In a series of 1055 noncardiac patients, none demonstrated this abnormality.¹¹⁵ Associated abnormalities include asplenia, polysplenia, and abnormal abdominal or cardiac situs.

CT or MRI reveals enlarged azygous and hemizygous systems in the upper abdomen and chest (Fig. 43-38).¹⁵⁸ These vessels may be confused with enlarged retrocrural lymph nodes, although their tubular nature and the brisk enhancement after bolus injection of contrast material usually allow for their correct identification. Cases of accessory azygous continuation of a left-sided IVC also have been reported (Fig. 43-39).⁶⁰

Venous Thrombosis

Thrombus formation may be detected in the IVC or its branches⁶⁹ (Figs. 43-40 and 43-41). Retroperitoneal tumor thrombus formation can be seen in patients with a multi-

Figure 43-38. Azygous continuation of the inferior vena cava. Nondynamically enhanced CT scan demonstrates marked enlargement of the azygos vein (arrow). The subhepatic, suprarenal portion of the inferior vena cava is absent.

Figure 43-39. Hemiazygos continuation of a left inferior vena cava. Nondynamically enhanced CT scan shows an enlarged hemiazygos vein (arrow) but a normal-sized azygos vein (arrow-head). The subhepatic, suprarenal portion of the inferior vena cava is absent. The liver is enlarged and heterogeneous because of the presence of infiltrative metastatic disease.

tude of various primary cancers. The most common include renal¹²¹ and adrenal cancers, but thrombi have also been demonstrated to be a result of direct extension of other primary neoplasms, including pancreatic cancers, sarcomas, and endocrine neoplasms. IVC thrombi may also be seen as an extension of lower extremity or pelvic deep vein thrombosis. Thrombi may occasionally be encountered in patients with coagulation disorders. Some of these patients with coagulopathy have isolated blood dyscrasias and others have paraneoplastic syndromes.

Gonadal vein thrombosis is being diagnosed with increasing frequency, probably because it is easy to identify with CT and MRI. Although gonadal vein thrombosis has been seen traditionally in postpartum women, in women with endometritis or pelvic inflammatory disease, or after gynecologic surgery (Fig. 43-42), it is now occasionally detected in patients with malignancies (particularly those

Figure 43-40. Inferior vena cava (IVC) thrombus. Dynamically enhanced CT scan shows the margin between the clot and the wall of the IVC to be sharply defined. Delayed images would not reveal any significant change in this appearance.

undergoing chemotherapy) (Fig. 43-43) and in patients with a variety of GI inflammatory diseases.^{113, 114} Patients with typical postpartum or postgynecologic surgery gonadal vein thrombosis have infected thrombi and must be given both antibiotics and anticoagulant agents. Appropriate treatment for patients with gonadal vein thrombosis related to malignancy or GI tract inflammation has not yet been determined with certainty; however, it appears that antibiotics are not indicated and anticoagulation is often unnecessary.^{113, 114}

In contrast to gonadal vein thrombosis, isolated septic thrombosis of the IVC is a rare finding, usually encountered in the critically ill. These patients must be managed aggressively with antibiotics and anticoagulants and, occasionally, even with surgical ligation of the IVC.

When imaging patients with suspected retroperitoneal venous thrombosis, the practitioner must determine not only whether a thrombus is present but also the extent of any thrombus that is identified. This information may be crucial for determining treatment. For example, it may be used to help direct subsequent IVC filter placement in a patient with a sterile inferior vena caval thrombus.¹⁰²

CT affords easy identification of a thrombus in retroperitoneal vessels. The involved vessel is usually enlarged on the CT scan. Prominent collateral vessels may be present. If IV contrast material has been administered, the thrombus itself is identified as a low-attenuation filling defect, in which case, a definitive diagnosis can be made without the need for any additional imaging (see Fig. 43-40). The wall of the thrombosed vessel enhances brightly. When a tumor thrombus is present, the tumor vessels within the thrombus can be seen to enhance, facilitating distinction from a bland thrombus (see Fig. 43-41).¹²¹

It is important not to confuse heterogeneous IVC enhancement (a *pseudothrombus*), often seen on early images of a dynamically enhanced CT scan, with a *thrombus* (Fig. 43-44). Such heterogeneous contrast enhancement is caused by the low attenuation of unenhanced centrally located blood (from the lower extremities and pelvis) surrounded by higher-attenuation enhanced blood (entering the IVC from the renal veins) on CT images obtained early in the course of a bolus injection of contrast material. Unenhanced central blood in a patient with this pseudothrombus is usually not nearly as well defined as is a true thrombus. Dynamic CT flow artifact disappears as time passes; it is not present if subsequent images are obtained.

MRI offers several advantages over CT in the assessment of potentially thrombosed veins:

1. Imaging can be performed in any plane.
2. IV contrast medium is not required.
3. Sensitivity, specificity, and accuracy of noncontrast MRI in detecting a venous thrombus are all exceedingly high (ranging between 97% and 98%).²⁴²

The accuracies of several noncontrast MRI techniques have been evaluated.^{9, 242} Although both spin-echo and gradient-echo images have high sensitivities, gradient-echo images are much more specific.²⁴² A combination of both techniques is most accurate.^{238, 242}

With MRI, errors in interpretation are most likely to be made when small, partially occluding thrombi are present.

Figure 43-41. Inferior vena cava thrombus. *A*, Coronal T1-weighted MR image of a large left renal cancer (C) in a 68-year-old man reveals a large amount of thrombus extending into the left renal vein (arrow) and inferior vena cava. *B*, A contrast-enhanced CT image through the inferior vena cava thrombus demonstrates it to be very heterogeneous because it contains areas of contrast enhancement. This indicates that tumor thrombus (which contains its own blood vessels) is present. Identification of a tumor thrombus, rather than a bland thrombus, does not necessarily alter subsequent treatment.

Figure 43-42. Gonadal vein thrombosis. *A*, Contrast-enhanced CT scan shows low-attenuation material within the lumen (arrow) of the right ovarian vein in a 22-year-old woman in whom a fever developed 24 hours after delivery. The wall of the vein is enhancing. The appearance is specific for venous thrombosis. *B*, A CT image through the pelvis reveals the enlarged uterus after delivery.

Figure 43-43. Gonadal vein thrombosis. *A*, Enhanced CT scan shows a low-attenuation clot in the right gonadal vein (arrow) of a patient with breast carcinoma. She had been receiving high-dose chemotherapy. *B*, On this enhanced CT scan from another patient with cancer, the thrombus is easily visualized in the left gonadal vein (arrow).

Figure 43-44. Inferior vena cava pseud thrombus. Early images on this dynamically enhanced CT scan demonstrate centrally, not yet enhanced inferior vena cava blood from the pelvis and lower extremities, surrounded by already enhanced blood from the renal veins. On delayed images, the inferior vena cava became homogeneous. Low-attenuation liver lesions are also present.

Occasionally, when spin-echo images are interpreted, false-negative diagnoses can be made because a low- to intermediate-signal-intensity thrombus can be mistaken for slowly flowing blood. In contrast, on spin-echo images false-positive diagnoses of thrombosis may result from misinterpretation of slowly flowing blood as thrombus; and on gradient-echo images, misdiagnosis may result from inability to detect high-intensity signal in small patent branch vessels.

MRI enhanced with gadolinium diethylenetriaminepenta-acetic acid (Gd-DTPA) can usually easily depict retroperitoneal venous thrombosis, particularly when the IVC is involved. Contrast-enhanced MRI can also be used to distinguish bland thrombi from tumor thrombi.⁷⁰ After contrast enhancement, the signal intensity of tumor thrombus may increase significantly in a fashion similar to that of the primary tumor.

MRI can identify the presence or absence of a thrombus, and with its multiplanar ability it is also extremely accurate in identifying the extent of tumor and components of a bland thrombus.¹²² It has also been suggested that MRI can determine the age of a thrombus. In a study by Soler and colleagues, an acute thrombus (clinically evident for less than 1 week) was seen to have homogeneous signal 86% of the time on spin-echo images.²³⁸ Heterogeneous signal intensity was seen in 75% of nonacute thrombi thought to be related to methemoglobin formation in the clot.

Inferior Vena Cava Filters

IVC filters may be indicated for the following:

1. Patients with lower extremity or pelvic venous thrombosis and recurring pulmonary emboli despite anticoagulation therapy.
2. Patients with lower extremity or pelvic venous thrombosis for whom anticoagulation therapy is contraindicated.²⁴⁷

3. Patients for whom anticoagulation therapy must be discontinued (e.g., because a complication has developed).²⁴⁷
4. Patients with a free-floating IVC thrombus even when anticoagulation agents can be safely administered.

A number of types of IVC filters are on the market. Most filters used today are permanent. The most well known is the Greenfield filter (Meditech/Boston Scientific, Watertown, Mass.). Others include the Vena-Tech filter (B. Braun Medical, Evanston, Ill.), the Simon Nitinol filter (Bard Radiology, Covington, Ga.), and the Bird's Nest filter (Cook, Bloomington, Ind.).

Temporary and retrievable filters have also been developed.¹⁶⁸ These filters must be removed within 2 weeks of insertion because after 3 weeks they become endothelialized.¹⁶³ The role of such devices is undefined, but they may be used increasingly in the future for short-term prophylaxis.

CT or MRI can be used to evaluate the retroperitoneal venous anatomy before IVC filter placement. This is done to identify the location and extent of any venous thrombi and to identify congenital abnormalities of the IVC and other veins in the abdomen that may affect the placement of the filter. For example, if there is a duplicated IVC, two separate filters may need to be placed (one in each infrarenal IVC).

CT is at least as accurate as venography in determining whether the filter is positioned at the proper level (Fig. 43-45). The normal filter position is usually between the IVC bifurcation and the renal veins. In some patients (e.g., those in whom thrombus extends more cephalad, as may occur in patients with renal cancer and renal vein and IVC tumor invasion), a suprarenal position may be safely used.¹⁰² CT and plain abdominal radiographs can also help determine whether the filter is appropriately angulated.¹⁶⁶

Complications of filter placement are not uncommon. It has been estimated that strut perforation may occur in as many as 40% of patients, although, fortunately, it is rarely symptomatic.⁵⁰ Filter malposition at the time of insertion

Figure 43-45. Inferior vena cava filter. Nondynamically enhanced CT scan shows that the metallic struts of this Greenfield filter are relatively evenly distributed, abutting all sides of the inferior vena cava.

Figure 43-46. Perforation of an inferior vena cava wall by an inferior vena cava filter. The Greenfield filter has migrated almost completely through the inferior vena cava. All of the struts are located either anteromedial to or along the anteromedial wall of the inferior vena cava.

is not infrequent, having been encountered in up to 10% of patients, and probably relates to the experience of the interventionalist.⁵⁰ CT can be used to identify these potential complications and others, including hematomas, pseudoaneurysms, infections, IVC occlusion, vessel disruption, incomplete filter opening, filter fractures, and migration (Fig. 43-46).²¹⁵

MRI can be performed safely in patients with an IVC filter. The newer Greenfield filters are made of titanium, which is less ferromagnetic than stainless steel. The Simon Nitinol filter is composed of a nickel and titanium alloy that is relatively nonferromagnetic.^{147, 264} Even filters that are ferromagnetic can be safely imaged. In vitro experiments have not detected any evidence that the small amount of magnetic torque that develops at a field strength of 1.5 T results in filter migration.^{147, 249} However, Liebman and colleagues caution that when filters are angulated, greater torque is exerted and the risk of filter movement increases.¹⁴⁷

Although MRI is at least as effective as CT in evaluating patients before filter placement, it is of little or no use in evaluation after filter insertion; this is partly because the filter is not directly seen. Instead, the imager can infer the position only by the presence of signal void. Furthermore, these magnetic susceptibility artifacts, which are caused by most filter types,²⁴⁹ degrade image quality to such an extent that abdominal MRI studies in these patients are of limited quality. In contrast, MRI of the head, pelvis, spine, and extremities is usually free of artifacts and can be performed without complication.²⁶⁴

Dilated Veins

Dilatation of the veins has several causes. Dilated azygos, hemiazygos, and lumbar veins may develop in

patients with IVC obstruction. In the presence of portal hypertension, the portal venous system may spontaneously decompress into the left renal vein or, more rarely, into the lumbar or gonadal veins, and the increased blood flow often causes vessel enlargement.²¹⁶ The gonadal veins may enlarge during pregnancy or may enlarge as a normal variant (see Fig. 43-33).²¹⁶

Normal retroaortic anastomoses between the azygos and hemiazygos veins may be prominent and may be confused with pathologic retrocrural nodes.²⁴⁸ Dilated retroperitoneal veins may occasionally be confused with enlarged para-aortic lymph nodes because both may have the same shape and distribution.⁶⁰ This is particularly true on CT examinations performed without IV contrast material or in those rare instances in which abnormal retroperitoneal lymph nodes enhance briskly (as with highly vascular retroperitoneal lymph node metastases). Fortunately, distinction between veins and lymph nodes is usually easily accomplished with contrast-enhanced CT and MRI (when any technique is used).

On enhanced CT studies, retroperitoneal veins are usually of much higher attenuation compared with retroperitoneal lymph nodes. On MR images, in most instances, patent veins are characterized by signal void on spin-echo sequences and high signal intensity on gradient-echo images. Sometimes, however, when flow through collateral vessels is slow or when retroperitoneal vessels are thrombosed, flow may not be demonstrated on either contrast-enhanced CT or MRI. The CT or gradient-echo MRI appearance of the retroperitoneal veins in these patients may mimic that of enlarged retroperitoneal lymph nodes.²³⁴

Small Inferior Vena Cava

Although the size of the IVC varies greatly, a flattening or significant decrease in the short-axis diameter of the IVC, giving it a slitlike appearance, is cause for concern. This has been observed on CT scans or MR images obtained in hypovolemic patients (see Fig. 43-21).¹¹⁶ The venous pressures of any trauma patient with this finding should be carefully monitored.

Primary Malignancies of the Inferior Vena Cava

Primary IVC malignancies are exceedingly rare. These tumors are most commonly found in middle-aged to elderly women. Leiomyosarcoma is the most frequently encountered cell type, although a primary malignant fibrous histiocytoma has been reported at least once.¹²⁵

Primary IVC leiomyosarcomas may produce intraluminal inferior vena caval abnormalities (thrombosis or vessel enlargement); however, extrinsic circumferential growth or the IVC without identifiable intraluminal extension is more common.²⁵ Thus, on CT scans or MR images, these tumors usually appear as bulky retroperitoneal masses centered around the IVC. The appearance is similar to that of other primary retroperitoneal malignancies that are not directly related to the IVC. The IVC may contain thrombus or be extrinsically occluded.

Figure 43-47. Infected inferior vena cava thrombus. Enhanced CT scan shows a punctate collection of air adjacent to inferior vena cava thrombus. This indicates infection in this patient with a right lower quadrant ostomy.

IV contrast enhancement is, at best, moderate because of the relative hypovascularity of most of these tumors.²⁵ Although leiomyosarcomas of the IVC grow slowly, they are associated with a poor prognosis.²⁷⁶ The prognosis is worst for tumors that are large at the time of presentation.²⁵

Pericaval Fat

Occasionally, fatty material can be identified adjacent to the IVC, most commonly in its intrahepatic portion. Although this finding can mimic a lipoma, it often merely represents localized pericaval fat (a normal variant).¹⁹⁶

Gas in the Inferior Vena Cava

On occasion, air or gas can be seen within the IVC (Fig. 43-47). Causes include recent intervention or line placement, an infected or septic thrombosis, or a bowel venous fistula. The air is usually readily identified by CT, but it can be more difficult to correctly identify with MRI, particularly on spin-echo images, in which it can be difficult to distinguish from signal void that is caused by flowing blood.

Lymph Nodes

Normal Anatomy

Normal retroperitoneal lymph nodes, commonly seen with CT, appear as small, soft tissue masses adjacent to the great vessels. Of the intra-abdominal nodes that can be identified, the retrocrural nodes are the most cephalic. Normal retrocrural nodes do not exceed 6 mm in diameter.⁵⁹ Occasionally, they may be confused with other retrocrural structures, including azygos and hemiazygos veins or their anastomoses, or the thoracic duct.

Para-aortic and *paracaval* lymph nodes usually are well visualized by CT because the great vessels are often surrounded by fat, allowing a sharp contrast between small lymph nodes and the surrounding retroperitoneum. Single para-aortic lymph nodes are considered normal on CT scans if they measure 10 mm or less in short-axis diameter.⁵⁹ Para-aortic lymph nodes may be confused with unopacified loops of small bowel and retroperitoneal nerves and vessels, including dilated or collateral veins (in particular, dilated left gonadal vein).

Pelvic lymph nodes are more difficult to identify than retrocrural or para-aortic nodes. They follow the iliac vessels, dividing into internal (hypogastric) and external iliac groups. Thus, pelvic lymph nodes may be confused with unopacified loops of bowel, tortuous iliac vessels, or adnexal masses in women. Of all the pelvic lymph nodes, the obturator nodes are the most important because they are the first site of lymph node spread from most pelvic tumors. These nodes, belonging to the external iliac chain, are best seen medially to the obturator internus muscle on CT images obtained just above the acetabula.

In general, as in the abdomen, all pelvic lymph nodes exceeding 10 mm in short-axis diameter should be considered abnormally enlarged^{128, 174}; however, some have suggested that the size cut-off for identifying pathologic lymph nodes in all but the external iliac chains should be lower. Vinnicombe and colleagues suggest that normal internal iliac lymph nodes should never exceed 7 mm in maximal short-axis diameter, obturator lymph nodes 8 mm in maximal short-axis diameter, and common iliac lymph nodes 9 mm in maximal short-axis diameter.²⁶²

Abnormalities of Lymph Nodes

In general, abnormal lymph nodes can be detected on CT or MRI only when their size is increased. Thus, although many diseases may produce lymph node pathology, there is tremendous overlap in their CT appearances.

In the text that follows, we discuss the use of various imaging modalities for evaluating abnormal retroperitoneal lymph nodes. Many processes that produce lymph node enlargement are discussed, including non-Hodgkin's and Hodgkin's lymphoma, and metastases from testicular cancer, prostate cancer, and other pelvic malignancies. Additionally, the significance of lymph node enlargement in patients with human immunodeficiency virus (HIV) infection is addressed. Benign causes of lymph node enlargement are also reviewed.

CT and MRI Technique

Computed Tomography

CT evaluation of retroperitoneal lymph nodes is most commonly performed in patients with a known or suspected malignancy to rule out malignant lymph node enlargement. Occasionally, CT is also performed to assess for retroperitoneal lymph node involvement in evaluation of patients with benign disease. CT demonstrates lymph node abnormalities only by identifying enlargement. It cannot detect tumor or inflammation in normal-sized lymph nodes.

CT scanning for evaluation of patients with possible retroperitoneal lymph node enlargement must be performed after administration of oral contrast material to maximally opacify any adjacent bowel. IV contrast medium is not mandatory but is helpful in distinguishing lymph nodes from vessels, especially in the pelvis. As is usually the case, contrast material should be injected as a dynamic bolus. Contiguous scans of 7- to 10-mm thickness are usually obtained from the diaphragm to the pubic symphysis.

Although most visualized retroperitoneal and pelvic lymph nodes over 10 mm in maximal short-axis diameter contain tumor cells, some do not; their enlargement may represent reactive hyperplasia, fatty replacement, reaction to chemotherapy or radiation therapy, or infection. In contrast, normal-sized lymph nodes may contain microscopic metastases that are missed by CT. This is particularly true in patients with Hodgkin's lymphoma and many of the primary pelvic malignancies.

Magnetic Resonance Imaging

Normally, lymph nodes have T1 values much longer than those of fat but only slightly longer than that of muscle. Lymph node T2 values are similar to those of fat but longer than that of muscle. Thus, lymph nodes show a signal intensity lower than that of fat on T1-weighted, spin-echo images but closer to that of fat on T2-weighted images. Lymph nodes in the midabdomen and upper abdomen are easily distinguished from retroperitoneal fat on T1-weighted, spin-echo sequences, and it is these images that are generally obtained for detection of enlarged retroperitoneal lymph nodes.

In the lower abdomen and pelvis, differentiation of lymph nodes from adjacent iliopsoas muscles may be more problematic. In these instances, T2-weighted images can be obtained for differentiation, since lymph nodes generally show considerably higher signal intensity than muscle on T2-weighted images.¹⁴⁰

Unlike CT, MRI allows easy distinction between lymph nodes and vessels on T1-weighted and T2-weighted, spin-echo sequences because normally flowing blood emits no signal. On occasion, however, it may be difficult to distinguish enlarged lymph nodes from adjacent bowel. For this reason, some have advocated use of oral MR contrast agents in problematic cases.⁶³

As with CT, untreated abnormal retroperitoneal lymph nodes can usually be reliably identified only on noncontrast MRI examinations and only by their abnormal size. In most cases, signal intensity criteria cannot be used to distinguish benign from malignant lymph nodes. In these instances, however, one potential advantage of MRI over CT is the ability of MRI to detect osseous or bone marrow involvement with greater sensitivity.¹⁰⁴

The only untreated neoplasm that may have typically different signal characteristics on unenhanced MRI examinations is metastatic melanoma. Lymph nodes infiltrated with melanoma often have high signal intensity on T1-weighted images, theoretically permitting identification of tumor even in normal-sized lymph nodes.

Still, noncontrast MRI may have potential advantages over CT in evaluating patients with treated lymph node

metastases because unenhanced MRI can sometimes distinguish residual tumor from fibrosis.^{184, 205} When treated tumor shows low signal intensity on T2-weighted images, it is likely that any residual masses primarily consist of fibrotic tumor and that little, if any, viable tumor remains. Conversely, treated lymph node masses that show high signal intensity on T2-weighted images may contain residual tumor. Unfortunately, this distinction is not absolute. Small foci of tumor may be present in predominantly fibrotic retroperitoneal lymph node masses that have low signal intensity on T2-weighted images. Similarly, high signal intensity on T2-weighted images may be detected in successfully treated lymph node masses for up to 12 months after successful therapy, presumably as a result of to edema.⁶³ Additionally, increased signal intensity on T2-weighted images may be the result of inflammation.

In comparison with unenhanced MRI for measurement of lymph node signal intensity changes, contrast-enhanced MRI may permit identification of some untreated tumor cells in both abnormal- and normal-sized retroperitoneal lymph nodes. Barentsz and associates found that dynamic gadolinium-enhanced lymph nodes that were infiltrated with metastatic bladder cancer enhanced more rapidly than did uninvolved lymph nodes.¹⁴ Metastatic lymph node enhancement was similar to that of the primary tumor. This difference permitted detection of metastatic tumor in some normal-sized lymph nodes in their series.

Detection of lymph node metastases may also be facilitated when another MR contrast agent, iron oxide, is administered.⁹³ Iron oxide particles are phagocytized and taken up in the lymphatic system. They accumulate in normal lymph nodes and thereby reduce lymph node signal intensity on T2-weighted or T2*-weighted images. Conversely, when lymph nodes are infiltrated with tumor, lymph node signal intensity either is not decreased or is heterogeneously decreased. In theory, this difference may also allow for MRI detection of nonenlarged metastatic lymph nodes. Unfortunately, there is some overlap, since some inflammatory lymph nodes do not demonstrate reduction in signal intensity on T2-weighted or T2*-weighted images.

Lymphography

In the past, lymphography was considered to be very valuable for evaluating patients with a wide variety of tumors because it demonstrated alterations in the internal architecture of normal-sized nodes as well as lymph node enlargement.¹⁵⁶ In recent years, however, the role of lymphography has been reduced dramatically. This is probably related as much to the decreasing expertise of most radiology departments in performing these "technically difficult" procedures as to the emergence of studies demonstrating that lymphography is not as clinically useful as was once thought.

As an example, lymphography has long been thought to be most useful in patients with Hodgkin lymphoma and with cervical and testicular carcinoma because of the propensity of these tumors to invade lymph nodes without enlarging them. Lipson and colleagues, however, found that of 39 patients with a low clinical stage of Hodgkin's

lymphoma and normal CT findings, 10 had positive lymphography results.¹⁴⁹ In only 2 of these 10 patients were the positive findings the result of tumor infiltration. In the other eight patients, the abnormalities were found to be caused by lymphoid hyperplasia at surgery, and these can be considered to represent false-positive diagnoses of tumor. The authors concluded that lymphography no longer has a role in the management of patients with Hodgkin's lymphoma.

CT and MRI have several important advantages over lymphography:

1. CT and MRI are able to image many more lymph node groups. Although lymphography opacifies most lymph nodes in the external and common iliac chains, the para-aortic, aortocaval, and paracaval nodes,¹¹⁷ the para-aortic nodes not immediately contiguous to the aorta and cava are often not visualized.¹⁷⁴ In addition, with lymphography, hypogastric and presacral pelvic nodes are opacified only occasionally, and retrocrural, renal hilar, splenic, peripancreatic, periportal, and mesenteric nodes are never filled with lymphographic contrast media.¹¹⁷ CT and MRI can be used to assess all of these lymph node groups.
2. CT and MRI can show other organs with possible tumor involvement (i.e., liver, spleen, adrenal glands).
3. CT and MRI can demonstrate the extent of local spread of a primary tumor.

Positron Emission Tomography

Positron emission tomography (PET), which is usually performed with either ¹⁸F-fluorodeoxyglucose (FDG) or ¹¹C-methionine, has shown great promise in identifying lymph nodes containing metastatic tumor (whether abnormally enlarged or normal in size) by detecting abnormally increased metabolic activity in tumor cells. In one series, for example, PET with ¹⁸F-FDG was more sensitive than CT in detecting lymph node regions involved with lymphoma.¹⁷² In this study, in the 740 lymph node regions evaluated, 160 diseased locations were identified by both CT and PET; however, PET depicted 25 additional involved areas (7 of which were confirmed histologically and 2 of which were believed to be false-positive diagnoses). CT demonstrated six additional abnormal lymph node regions, at least three of which were ultimately found to be false-positive diagnoses.

The degree of metabolic activity of lymphomatous lymph nodes identified on PET studies has also been shown to correlate with disease activity and patient prognosis.²¹⁸

CT-Guided and MRI-Guided Biopsy

CT-guided biopsy of abnormally enlarged retroperitoneal lymph nodes is easily performed. Biopsy of potentially lymphomatous masses should be performed with core (not aspiration) biopsy needles because pathologists often require histologic rather than cytologic specimens for accurate tumor characterization and grading. Core biopsy material is usually placed in sterile saline rather than Formalin to allow specific tissue analyses to be performed. CT fluo-

roscopy, which is being performed at an increasing number of institutions, can result in a quicker biopsy procedure.

MRI-guided biopsy of suspected pelvic lymph nodes is also usually easily performed.¹³ MRI guidance is more expensive, and many radiology departments are not equipped to do biopsies in the MR suite because nonferromagnetic biopsy needles, among other items, are necessary; however, MRI offers the potential advantage over CT of allowing imaging in nonstandard planes.

Lymphoid Malignancies

Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma (NHL) comprises a diverse group of lymphocytic neoplasms. Certain populations are particularly susceptible to NHL. Patients who have had renal transplants, patients with acquired immunodeficiency syndrome (AIDS), and patients who are immunocompromised for other reasons are all at increased risk.

Lymphomas are generally classified as low-grade, intermediate-grade, or high-grade, although controversies about classification continue.²¹⁸ Low-grade lymphomas are often disseminated widely when first detected, yet they are slow-growing and patients may survive for years after diagnosis. Treatment may be deferred initially. Chemotherapy and radiation therapy are used for palliation and not cure. Over time, these neoplasms may occasionally transform into high-grade lymphomas.

Intermediate-grade or high-grade lymphomas are less often widespread when discovered but are much more aggressive. Potent chemotherapy is required, and the goal of treatment is remission or even cure. Five-year survival statistics are much lower for these lymphomas (23% to 45%) than for low-grade lymphomas (50% to 70%).

Lymphomas are staged according to the Ann Arbor system as follows:

Stage I disease: involvement of one lymph node group

Stage II disease: involvement of more than one lymph node group on the same side of the diaphragm

Stage III disease: involvement of lymph nodes on both sides of the diaphragm

Stage IV disease: spread outside the lymphatic system

Patients with symptoms such as weight loss, nocturnal sweating, and/or fever are considered to have "B" disease; those without these symptoms are considered to have "A" disease.

CT and MRI at Presentation

CT has been the preferred imaging modality for evaluation of the retroperitoneum in patients presenting with NHL because the involved nodes are usually enlarged. CT is strongly advocated for measuring the extent of the lymphoma prior to initiation of treatment. It can be of great assistance in planning ports for radiation therapy.²⁶

Most patients with NHL (compared with fewer than half with Hodgkin lymphoma) have abdominal involvement. Bulky para-aortic lymph node enlargement is common. CT easily detects the enlarged retroperitoneal lymph nodes (Fig. 43–48). Mesenteric disease, which is seen in more

Figure 43-48. Non-Hodgkin lymphoma. Dynamically enhanced CT scan shows large lymph node masses in the para-aortic lymph node chains. The inferior vena cava is displaced anteriorly.

than half of the patients (versus fewer than 5% of those with Hodgkin disease), is also easily visualized.¹⁷⁴ The detected enlarged lymph nodes may appear as discrete masses or as confluent soft tissue obliterating the retroperitoneal fat, resulting in loss of definition of the fat planes between the aorta and the IVC. Many other lymph node groups (in addition to para-aortic lymph nodes), such as retrocrural, gastrohepatic, paraceliac, periportal, peripancreatic, posterior iliac crest, and pelvic chains, are frequently involved.^{36, 61}

Although most enlarged lymphomatous lymph nodes show an attenuation similar to that of muscle on contrast-enhanced CT scans and are therefore easily distinguished from adjacent vessels, others may demonstrate enhancement that is similar to that of the retroperitoneal and pelvic vasculature. In one study, for example, 4 of 25 patients with lymphoma demonstrated lymph nodes that enhanced by a mean of about 60 Hounsfield units (HU) after injection of contrast material.²⁰⁴

CT can also be helpful in evaluating the specific group of patients with cutaneous T-cell lymphomas (except those with low-grade mycosis fungoides, in whom positive CT findings are unusual). Abnormal CT findings have been detected in nearly one third of these patients.¹⁵ Lymph node abnormalities often consist of an increased number of normal-sized lymph nodes, which can occasionally be located in the retroperitoneum, although axillary and inguinal lymph nodes are most commonly involved. The involved lymph nodes may contain lymphoma or may be reactive (e.g., in dermatopathic adenopathy), and the prognosis is adversely affected in either case.¹⁵

MRI demonstrates enlarged lymphomatous lymph nodes with an accuracy comparable to that of CT, again facilitating staging (Fig. 43-49). In one study, MRI was actually superior to the combination of CT and bone marrow biopsy; it detected enlarged lymph nodes that were seen on CT as well as focal areas of marrow involvement that would not have been detected during standard iliac wing bone marrow sampling.¹⁰⁴

CT and MRI for Follow-up of Non-Hodgkin Lymphoma

CT and MRI are commonly used to follow disease after treatment, with CT the preferred study at most institutions. Response to treatment is usually indicated by a reduction in overall abdominal lymph node enlargement, which can often be quite dramatic.¹⁹² Increased retroperitoneal and mesenteric stranding is commonly noted in these patients (Fig. 43-50).

In some patients, lymph node attenuation values may decrease as an appropriate response to treatment with or without overall reduction in lymph node size and/or increased mesenteric stranding. Post-treatment dystrophic calcification of lymphomatous masses is also encountered occasionally.¹³⁷

In some patients, treatment does not completely eradicate the lymphoma and persistent enlarged involved lymph nodes are demonstrated on CT. Conversely, it is not uncommon for patients with lymphoma who have responded to therapy to have post-treatment inflammatory or fibrotic masses containing no identifiable residual tumor.¹⁴⁵ In general, the larger the lymphomatous masses are before treatment, the larger the residual fibrotic masses will be after treatment.²¹⁸

Thus, in patients with treated NHL, failure to completely eradicate retroperitoneal lymph node masses does not necessarily indicate that viable tumor cells are present. Residual masses after treatment can either be benign or contain persistent tumor. Unfortunately, there are no CT characteristics that reliably allow differentiation between benign and malignant residual masses. Patients with residual masses after treatment should be monitored closely on follow-up examinations to determine whether these masses remain stable over time, which would indicate that they are probably benign.

As noted, several studies have found that MRI may be helpful in distinguishing residual tumor from fibrosis. Many tumor masses remain bright on T2-weighted images, and chronic fibrosis or scar is often dark (see Lee and Glazer¹⁴¹). In some instances, MRI might be helpful in evaluating patients in whom recurrent or residual tumor is suspected despite stable CT findings. Unfortunately, there is much overlap. Although low-signal-intensity residual masses on T2-weighted images are unlikely to contain viable tumor, high signal intensity in residual masses on T2-weighted images can result from viable tumor or from a number of benign causes, including inflammation and edema. PET has shown greater promise in this area, occasionally revealing residual tumor because of its greater metabolic activity.²¹⁸

HIV-Related Non-Hodgkin Lymphoma

HIV-related NHL is often characterized by exuberant lymph node enlargement, which is often widespread. Abdominal visceral organ involvement (resulting in hepatic, splenic, and GI tract masses) and omental disease are much more commonly seen than in other lymphoma patients.²⁵⁶ AIDS-related lymphomas tend to be poorly differentiated and aggressive. Advanced disease is often present at the time of diagnosis, and the prognosis is poor.

Figure 43-49. Non-Hodgkin lymphoma. A, T1-weighted MR image reveals a small, intermediate-signal-intensity mass surrounding the left renal artery. Lymphomatous masses are often considered to be “soft” neoplasms and frequently surround retroperitoneal vessels and the ureters without obstructing them. B, On a T2-weighted image in the same patient, the mass is typically hyperintense. C, The mass also demonstrates increased signal intensity on T1-weighted, gadolinium-enhanced images.

Figure 43-50. Treated non-Hodgkin lymphoma. Contrast-enhanced CT scan demonstrates residual soft tissue in the para-aortic and paracaval regions of the retroperitoneum in a patient who has undergone chemotherapy. The poorly defined soft tissue stranding is frequently identified in patients with treated lymphoma. Although all of the remaining tissue might represent fibrosis, the possibility of residual viable tumor cannot be excluded. In this patient, the soft tissue remained stable on scans over several years, suggesting that no residual tumor was present.

Hodgkin Lymphoma

Hodgkin's lymphoma is more common in adults in higher socioeconomic groups and peaks in both the third and the fifth decades of life. The hallmark of Hodgkin lymphoma is the Reed-Sternberg cell. Unfortunately, this cell is relatively uncommon in pathologic specimens, and aspiration biopsies are often inadequate for establishing the diagnosis.³⁵

Histologically, Hodgkin lymphoma is classified into several forms. The *nodular sclerosing* type is most frequent (50% to 80% of cases) and of intermediate aggressiveness. *Lymphocyte-predominant* Hodgkin lymphoma, which carries the best prognosis, and *lymphocyte-depletion* Hodgkin lymphoma, which carries the worst, are considerably less common (5% to 10% each). The *mixed cellularity* forms occur with somewhat higher frequencies (15% to 40%).³⁵ Staging of Hodgkin lymphoma is similar to that of NHL.

CT is now used for pretreatment evaluation of nearly all patients with Hodgkin lymphoma. Staging laparotomies for Hodgkin lymphoma are performed only infrequently today. Hodgkin lymphoma tends to spread by involving contiguous lymph nodes. This pattern of spread contrasts with that of NHL, in which many different and widely separated lymph node chains can be involved at the same time. For this reason, when abdominal CT examinations are performed in patients with thoracic Hodgkin disease, the upper abdominal lymph nodes must be carefully scrutinized. Involvement of lower abdominal or pelvic lymph

nodes is unlikely unless the upper abdominal lymph nodes are also involved.

Lymph node involvement in Hodgkin's disease, in contrast to that in NHL, less commonly results in bulky enlargement. Therefore, unfortunately, CT and MRI are less sensitive in detecting abdominal spread. This has led to the recommendation by some (e.g., Castellino and coworkers³⁴) that lymphography be performed instead of CT or MRI for evaluation of patients with Hodgkin lymphoma even though others now think that lymphography no longer has any role in the workup of patients with this disease.¹⁴⁹ While lymphography may still play a role in the evaluation of some patients with Hodgkin lymphoma, CT is generally performed before lymphography, and lymphography is restricted to patients with negative CT findings. Lymphography is not used at many institutions today because experience in performing this procedure is very limited. PET may eventually serve as an effective replacement.

CT and MRI can also be used to evaluate possible splenic involvement. Unfortunately, correlation between spleen size and splenic Hodgkin lymphoma is poor. Only about one third of patients with splenomegaly have splenic involvement, whereas one third of patients with normal-sized spleens have intrasplenic spread of Hodgkin lymphoma.¹ Only massive splenomegaly correlates well with the spread of Hodgkin disease. Single or multiple discrete, low-attenuation masses detectable by CT are seen infrequently.

Treatment of Hodgkin lymphoma that is confined to the mediastinum usually consists of radiation therapy, which can be curative when all areas of tumor involvement are included in the radiation port.³³ In advanced disease, chemotherapy and radiation therapy are often used jointly, often with favorable results. The 10-year survival rate has been reported at 85% in adults.³⁵ For this reason, careful follow-up of patients over many years is required.

Other Lymphoid Malignancies

Retroperitoneal and pelvic lymph node enlargement can be encountered in many patients with *Waldenström's macroglobulinemia*, a low-grade lymphoid malignancy that is encountered only rarely, usually in older adults. Clinically, patients typically present with fatigue, weight loss, hepatosplenomegaly, and peripheral lymph node enlargement.

Imaging studies commonly detect hepatosplenomegaly and enlarged lymph nodes as well as bone marrow involvement; the bone marrow involvement is best assessed by MRI. In one study, enlarged lymph nodes were noted in 10 (43%) of 23 patients with this disease, with multiple lymph node groups being involved in most instances (usually the retrocrural, para-aortic, iliac, and inguinal lymph node chains).¹⁸⁰ On lymphography, these lymph nodes usually appear hyperplastic.

Testicular Neoplasms

Testicular tumors are the most common cancers in men between the ages of 15 and 34 years.⁶² Recent advances in therapeutic regimens have met with excellent success in prolonging patient survival.

Testicular neoplasms are divided into *germinal* and *non-germinal* cell types. The most common germinal tumor is the *seminoma*. Seminomas are extremely responsive to radiation, and for this reason retroperitoneal surgery (lymph node dissection) and chemotherapy are reserved for patients with advanced disease. The lack of routine lymphadenectomy after orchiectomy in these patients explains why there is some difficulty in acquiring data on the accuracy of CT in staging. Surgical follow-up is rarely available.

The nonseminomatous germ cell tumors include teratocarcinoma, teratoma, choriocarcinoma, embryonal cell neoplasms, and yolk sac tumors. Mixed cancers containing seminomatous and nonseminomatous elements may also be considered in this group because the clinical course often follows that of the nonseminomatous cells.⁶² Although some testicular tumors appear quite homogeneous on CT and MRI scans, teratomatous neoplasms often appear heterogeneous because they contain areas of necrosis, fat, and calcification (Fig. 43–51). These neoplasms have been treated by orchiectomy followed by staging lymphadenectomy in many institutions.

Lymphatics from the testicle drain into ipsilateral para-aortic midabdominal lymph nodes near the renal vein insertions. Only rarely do testicular lymphatics drain into ipsilateral external iliac nodes. Lymph node metastases from testicular neoplasms, therefore, tend to develop first in these "landing zones" rather than in pelvic lymph nodes. Specifically, the landing zone for left testicular tumors is in the left para-aortic region just caudad to the level of the left renal vein; for right testicular tumors, it is in the right paracaval region, just caudad to the level of the right renal vein. When CT or MRI scans are being reviewed in patients with testicular cancers, it is imperative that these regions be scrutinized for lymph node enlargement.

Although testicular metastases often enlarge involved nodes, tumor spread is found in normal-sized nodes in many instances.¹²⁸ Furthermore, the lymph node enlargement seen on CT scans is occasionally not caused by spread of tumor. Thus, the detection rate of lymph node metastases by both CT and MRI has been disappointing.

Figure 43–51. Metastatic testicular teratocarcinoma. Nondynamically enhanced CT scan shows retroperitoneal lymph node metastases. Huge nodal masses with areas of fat, fluid, and calcification are characteristic.

In general, lymph node status is appropriately assessed in only about 70% of patients.^{32, 131} The errors probably result primarily from the inability of CT to identify microscopic lymph node metastases; however, false-positive diagnoses are not uncommon. In one study, for example, CT failed to detect any enlarged lymph nodes in 49 patients with nonseminomatous germ cell tumors, 18 of whom were found to have lymph node metastases at lymph node dissection.³² Furthermore, of 15 patients in whom CT showed enlarged lymph nodes, only 7 were confirmed to have lymph node metastases at surgery.

False-negative and false-positive diagnoses have not decreased dramatically in the past few years, even though image quality has improved with the use of third-generation, fourth-generation, and now helical and multidetector CT scanners. For example, in a study that included 201 patients with testicular cancer, state-of-the-art CT in patients with clinically localized nonseminomatous germ cell tumors still had a 33% false-negative rate for detecting involved lymph nodes.¹⁷⁹ To reduce the number of false-negative scans, these authors suggested that identification of any lymph node (no matter what the size) in the landing zone areas should be considered suspect.

In another series, 143 CT examinations were performed on patients with low-stage nonseminomatous germ cell tumors.¹⁴² It was found that when a size threshold of 10 mm was used, the false-negative rate for diagnosis of lymph node metastases in the landing zones was 25%. In contrast, the sensitivity in detecting metastatic lymph nodes increased to over 90% and the negative predictive value to over 90% when any visualized lymph nodes (regardless of size) in the landing zone of a known testicular primary neoplasm were considered abnormal. Certainly, such an increase in sensitivity and negative predictive value comes at the expense of low specificity (~50%) and positive predictive value (~50%).

In summary, unless size criteria are reduced or eliminated, CT and MRI are not exceedingly sensitive for detecting lymph node metastases in patients with testicular cancer. CT and MRI appear to be most accurate in these patients when they identify enlarged lymph nodes. False-positive diagnoses are considerably less common than false-negative diagnoses. Interestingly, PET has also been somewhat disappointing in these patients because ¹⁸F-FDG may not be taken up in metastases that contain extensive, well-differentiated teratomatous cells.¹³¹

In many patients, lymph node metastases from testicular cancer show soft tissue attenuation on CT scans; however, low-attenuation lymph node masses (<30 HU) are occasionally encountered. In one series, 10 of 57 patients evaluated by CT had such masses.²²⁷ Low-attenuation lymph nodes in patients with NHL are nearly always the result of treatment; however, they may be encountered in untreated patients with testicular cancer. Such low-attenuation lymph nodes often contain teratomatous elements, often reflecting cellular components of the primary tumor.

Residual masses, which may be of soft tissue or of low (near-water) attenuation, have been detected in patients with testicular cancer after apparently successful treatment (Fig. 43–52). As in patients with NHL, the persistence of these masses does not necessarily indicate that malignant or even benign teratomatous cells remain, and this can

Figure 43–52. Retroperitoneal teratoma after treatment of metastatic testicular cancer. Contrast-enhanced CT scan demonstrates a large, predominantly cystic mass in the left para-aortic region in a young patient who had undergone orchiectomy and chemotherapy for testicular cancer. On the basis of the CT appearance, this mass might represent malignant disease (teratocarcinoma), teratoma, or fibrosis and necrosis. At surgery, this mass was found to represent a teratoma.

sometimes be a problem.²⁴⁰ Follow-up CT examinations cannot distinguish among three possibilities: (1) residual cancer, (2) residual benign teratoma, or (3) fibrosis. Differentiation is important because treatment varies for each of these three types of masses. Patients with residual malignant tumor cells must receive additional chemotherapy. Benign mature teratomas, which may develop from treated malignant nonseminomatous germ cell tumors, must be surgically removed because they may undergo malignant transformation. Treatment of purely fibrotic masses is not warranted. In any given case, CT features do not reliably permit distinction of one of these masses from another.²⁴⁴ MRI has not proved any more helpful than CT in facilitating these distinctions to date.

We recommend that patients with testicular neoplasms be followed up with serial CT examinations and serum tumor markers. Percutaneous fine-needle aspiration biopsy can be performed on a residual mass if a patient has rising markers or if the mass has changed in size or morphologic features. In many cases, surgery is required for diagnosis.

Prostate Cancer

Accuracy of CT and MRI in detecting lymph node metastases from prostate cancer has been disappointing, with sensitivities ranging from 27% to 75% and specificities from 66% to 100%.¹⁹⁴ In contrast, local staging of prostate cancer with endorectal coil MRI is considered to be far more accurate. It is thought that the primary reason for the low accuracy rate of CT and MRI in detecting lymph node metastases is that prostate cancer can spread to retroperitoneal lymph nodes without enlarging them; thus, metastatic disease is undetectable on CT or MRI, leading to many false-negative diagnoses.

Some authors have suggested that CT accuracy in lymph node staging of prostate cancer might be increased by

lowering the threshold for identifying lymph node enlargement and by generous performance of percutaneous biopsy. In their series of 285 patients with clinically localized prostate cancer, Oyen and colleagues considered all lymph nodes measuring 6 mm or more to be abnormal.¹⁹⁴ This would be expected to increase both true- and false-positive rates; however, percutaneous biopsy of one lymph node was performed in each patient in whom at least one abnormal lymph node was identified. Positive biopsy results were required to confirm the presence of metastatic disease. Use of biopsy along with the lower size threshold for detecting suspected lymph node metastases reduced the number of false-positive diagnoses. With this combination of techniques, sensitivity, specificity, and accuracy in detecting lymph node metastases from prostate cancer improved to 77.8%, 100%, and 96.5%, respectively. Although these results are intriguing, it is not yet clear that such considerable effort is warranted in all patients with this common pelvic malignancy.

Despite the relatively low accuracy of CT in local staging of prostate cancer and in detecting lymph node metastases from prostate cancer, many physicians request that staging CT be performed prior to treatment. In an attempt to limit the number of CT examinations that are requested, many urologists restrict the use of CT to patients with elevated serum prostate-specific antigen (PSA) levels. Indeed, it has been found that in an asymptomatic patient with a newly diagnosed and untreated prostate cancer, the likelihood of abdominal and pelvic CT demonstrating an abnormal finding is extremely low (<1%) if the serum PSA level is 20 ng/mL or lower.¹⁰⁹ When the serum PSA is elevated above 20 ng/mL, however, abnormal CT findings are detected in more than 10% of patients.¹⁰⁹

CT and MRI are occasionally performed for follow-up evaluation of patients with prostate cancer after therapy. For example, images can be obtained to assess response of previously diagnosed lymph node metastases to hormonal therapy (Fig. 43–53).

Follow-up imaging has been performed in patients treated with a combination of transperineal radioactive seed implantation and laparoscopic lymph node dissection. In a study of 73 patients, 42 were found to have low-attenuation masses along abdominal and pelvic lymph node chains; these masses resembled necrotic lymph nodes but were subsequently believed to represent lymphoceles.⁷² Awareness of this possible finding may reduce the number of false-positive diagnoses in these patients.

Other Malignancies

Retroperitoneal lymph node enlargement can also be encountered in patients with renal cell cancer (Fig. 43–54). Other pelvic tumors that commonly metastasize to pelvic and retroperitoneal lymph nodes are bladder, endometrial, and cervical carcinomas; less often, metastases may come from ovarian carcinomas.⁹⁶ Although the local manifestations of all of these pelvic tumors appear to be better assessed with MRI than with CT, both modalities appear equally effective in detecting retroperitoneal lymph node metastases.

CT and MRI are usually helpful only when bulky meta-

Figure 43–53. Prostate cancer metastatic to retroperitoneal lymph nodes. Contrast-enhanced axial CT image demonstrates a large lymph node metastasis in the left para-aortic region (arrow) of a 60-year-old man. This lymph node can be followed on serial CT scans once hormonal therapy is instituted.

static disease is present. Unfortunately, these pelvic neoplasms frequently metastasize to normal-sized or only slightly enlarged nodes, so that identification of tumor spread to pelvic and retroperitoneal nodes by CT and even MRI is often impossible.¹²⁸ Reported sensitivities for detecting abdominal and pelvic lymph node involvement range from 30% to 100% for bladder cancer and from 80% to 85% for cervical cancer. Specificities have also been less than optimal, ranging from 46% to 100%.^{117, 265, 267} Detection of lymph node involvement in some patients (with cervical carcinoma) has not been substantially improved even when high-resolution MRI is performed with phase-array coils.⁹⁶

Some work has demonstrated that MRI lymph node enhancement with gadolinium-based contrast material is more rapid when metastases from bladder cancer are pres-

Figure 43–54. Retroperitoneal, para-aortic lymph node enlargement resulting from metastases due to a large left renal adenocarcinoma (M), as seen on a dynamically enhanced CT scan.

ent.¹⁴ This difference in enhancement rate between lymph nodes that contain tumor and those that do not has resulted in MRI detection of metastatic disease even in normal-sized lymph nodes. On CT scans, however, lymph nodes invaded with metastatic tumor occasionally enhance with contrast material to the same extent as adjacent vessels. Such enhancement, which has been observed in some patients with bladder cancer¹¹⁰ and some with other nonpelvic primary neoplasms (e.g., thyroid, renal, oat cell cancer and carcinoid),²⁰⁴ may lead to the erroneous impression that the lymph nodes actually represent abnormal dilated vessels.

Currently, lymphography (followed by percutaneous biopsy of suspect nodes) is rarely performed in patients with cervical cancer whose cross-sectional imaging studies do not demonstrate metastatic disease. Lymphography is not used in patients with bladder, prostate, ovarian, or endometrial cancer. Any of these patients whose CT findings do not demonstrate metastatic disease must proceed to staging lymphadenectomy either at laparotomy or via laparoscopy.

Enlarged Lymph Nodes in HIV Infection

Enlarged abdominal lymph nodes are present in most (>60%) patients with HIV infection.^{39, 209, 225} Lymph node enlargement is commonly not massive. In about 50% of all patients, the short-axis diameter of the largest lymph node measures only 10 to 15 mm.²⁰⁹ Although in some HIV-infected patients, enlargement results only from reactive hyperplasia, many other diseases may be responsible.³⁹ For this reason, it has been recommended that lymph node biopsy be considered in any symptomatic patient with enlarged lymph nodes in whom no known cause of lymph node enlargement exists (other than HIV infection itself).²⁰⁹

Studies have demonstrated that when abdominal CT is performed in symptomatic HIV-infected patients, a cause of patient symptoms can be demonstrated in nearly 70% of instances.²²⁵ Thus, CT often contributes to patient management, although it rarely leads directly to patient diagnosis. In patients with fever of unknown origin, however, CT appears to assist in patient management in a minority of cases.²²⁵

Occasionally, the CT characteristics of the enlarged lymph nodes and the identification or lack of identification of specific additional findings may facilitate a more focused differential diagnosis. For example, when lymph nodes are of homogeneous soft tissue attenuation (Fig. 43–55), the most likely diagnosis is *Mycobacterium avium* complex (MAC) infection or AIDS-related NHL.²⁰⁹ Other, less common causes of enlarged, soft tissue–attenuation lymph nodes include Kaposi's sarcoma, disseminated histoplasmosis, and Hodgkin's lymphoma.

M. avium complex infections generally occur only in patients in advanced stages of AIDS with very low CD4⁺ lymphocyte counts (50 cells/ μ L or less). Although patients with mycobacterial infections can have enlarged retroperitoneal lymph nodes, they usually have disproportionately larger mesenteric lymph nodes.^{108, 208}

When IV contrast-enhanced scans of lymph nodes in HIV-infected patients show central or diffuse low attenuation (Fig. 43–56), disseminated *M. tuberculosis* infection is the most likely cause; lymphoma, *M. avium* complex infec-

Figure 43–55. *Mycobacterium avium*–*intracellulare* in a patient with human immunodeficiency virus (HIV) infection and a low CD4⁺ count. Enlarged para-aortic and paracaval lymph nodes (arrows) along with a large mesenteric mass (m) are identified on this CT nondynamically enhanced scan. The lymph nodes show characteristic soft tissue attenuation. Low-attenuation lymph nodes are more commonly seen in patients with tuberculosis.

tion, histoplasmosis, and coccidioidomycosis are less likely.²⁰⁹ More than 80% of patients with tuberculosis have enlarged lymph nodes, some or all of which are of diminished attenuation.^{208, 209} Many patients with tuberculosis also have small, low-attenuation visceral organ lesions.

When enhancement of lymph nodes in HIV-infected patients shows them to have densities comparable to or higher than those of adjacent muscles, a diagnosis of Kaposi's sarcoma should be considered. Lymph nodes involved with Kaposi's sarcoma are often quite hyperenhancing, probably because of their vascularity.²⁰⁹ In one series,

Figure 43–56. *Mycobacterium tuberculosis* infection in a 50-year-old man with human immunodeficiency virus (HIV) infection. Enlarged, low-attenuation lymph nodes are identified on this contrast-enhanced CT image in the periportal, portocaval, and paraceliac regions (arrows).

lymph nodes that were enlarged because patients had the generalized form of Kaposi's sarcoma enhanced to a higher attenuation value than for adjacent muscles in 26 of 38 patients.¹⁰¹ The authors suggest that whenever briskly enhancing lymph nodes are encountered, a diagnosis of Kaposi's sarcoma should be considered even when no such diagnosis has previously been made.

When calcifications are noted in lymph nodes, extrapulmonary *Pneumocystis carinii* infection is likely. Other associated findings of extrapulmonary pneumocystis infection include multiple focal low-attenuation splenic lesions, liver lesions, and pleural and peritoneal fluid.¹⁵² Calcification has been noted to develop over time in all of these structures as well as in the renal cortices and adrenal glands. Visceral organ calcifications have also been reported to develop in rare patients with disseminated *M. avium* complex and cytomegalovirus infections.²⁰⁹

When lymph node enlargement is massive (with maximal diameters exceeding 3 cm, for example), lymphoma becomes the most likely diagnosis.²⁰⁹

Benign Causes of Retroperitoneal Lymphadenopathy

The presence of enlarged retroperitoneal lymph nodes is certainly not definitively diagnostic of malignancy. Occasionally, enlarged lymph nodes, seen on CT or MRI scans in patients with lymphomas or pelvic neoplasms, contain only reactive hyperplasia. Although hyperplastic lymph nodes can undergo fatty replacement, which has a characteristic appearance on CT or MRI scans, this finding is frequently absent.

Several inflammatory diseases have been specifically identified as causing, or being associated with, retroperitoneal lymph node enlargement. Benign enlarged lymph nodes are not uncommonly detected in patients with end-stage cirrhosis; in one series, they were identified in as many as 50% of patients.⁵⁸ Interestingly, lymph node en-

largement is encountered at the highest frequency in patients with cirrhosis related to biliary tract disease. They have been seen in 86% of patients with primary biliary cirrhosis, 69% of patients with primary sclerosing cholangitis, and 64% of patients with cryptogenic biliary cirrhosis.⁵⁸ In comparison, lymph node enlargement is noted at the lowest frequency in patients with hepatitis or alcohol-induced cirrhosis (46% and 37%, respectively).⁵⁸ Although the enlarged lymph nodes associated with liver disease are most commonly seen in the periportal and portacaval spaces, they can also be identified in the retroperitoneum.

Retroperitoneal lymph node enlargement may also be encountered in patients with mycobacterial infections (with or without concomitant HIV infection). In these patients, mesenteric and peripancreatic lymph node enlargement frequently overshadows enlargement of the retroperitoneal nodes, perhaps reflecting the drainage routes of hematogenously seeded GI tract organs. As already described, in a significant minority of patients with tuberculosis (up to 40%), enlarged lymph nodes have low-attenuation centers, a finding that occurs in some patients with malignant disease as well as in patients with other bacterial infections, Whipple's disease, and lymphangioleiomyomatosis.^{101, 108, 208, 209}

Enlarged retroperitoneal lymph nodes have also been observed in patients with sarcoidosis (Fig. 43–57).¹¹ In one series, lymph node enlargement was detected in 16 (31%) of 52 patients with this disease whose CT scans were obtained through the upper abdomen and midabdomen.²⁶³ In several older studies, lymph node enlargement had been identified much more frequently, in 60% to 75% patients.^{11, 164} The porta hepatis and para-aortic retroperitoneal lymph nodes are most commonly affected.

Interestingly, only rarely is abdominal lymph node enlargement present without mediastinal lymph node involvement. Further, although the extent of abdominal and pelvic CT findings is often related to clinical disease activity, these findings do not necessarily correlate with the chest radiographic stage. This indicates that abdominal involvement and chest involvement may occur at different times and with differing severities.

Figure 43–57. Retroperitoneal lymph node enlargement in a 41-year-old patient with sarcoidosis. *A*, Unenhanced CT image demonstrates multiple, mildly enlarged lymph nodes in the para-aortic region of the retroperitoneum. *B*, CT image at the upper abdomen level reveals a massively enlarged spleen and several mildly enlarged retrocrural lymph nodes. All of these abnormalities are a result of sarcoidosis.

Castleman disease is occasionally also associated with development of enlarged retroperitoneal fibrotic masses or nodes.⁸³ In many cases, the CT or MRI appearance of these enlarged lymph nodes is not specific. It has been suggested, however, that identification of intense and uniform contrast enhancement in lymph nodes can suggest the diagnosis, since such enhancement is uncommon in lymph nodes involved with metastatic tumor (which are most often from hypovascular pelvic primaries rather than from Kaposi's sarcoma) or with infections.⁸³ When seen in Castleman's disease, brisk lymph node enhancement usually indicates presence of the localized and more commonly encountered hyaline-vascular type (occurring in 90% of patients) rather than of the plasma-cell type.

In rare instances, patients with primary or secondary amyloidosis may have involved retroperitoneal or pelvic lymph nodes, which can enlarge to massive size.^{74, 231} In some patients, the lymph node enlargement can represent the dominant or the only site of disease. The appearance of lymph node enlargement resulting from amyloidosis is not specific, although several case reports have noted that irregularly speckled calcifications may develop, as shown by Segalov and colleagues.²³¹

Bulky retroperitoneal lymph node enlargement can also be encountered in patients with lymphangiomyomatosis. This rare disease, in which smooth muscle proliferation occurs in lymph nodes and lymphatics, usually affects young women of childbearing age. Although benign, this disease is often relentlessly progressive. Some patients may be stabilized with medical therapy; however, many who are treated for years eventually die of respiratory failure secondary to the characteristic pulmonary involvement unless lung transplantation can be performed. On abdominal and pelvic CT scans, the enlarged lymph nodes may show cystic, low-attenuation components. In fact, when bulky, enlarged lymph nodes are identified in a young woman of childbearing age and when these lymph nodes contain areas that show low (near-water) attenuation, a diagnosis of lymphangiomyomatosis should be suggested.²⁷¹

Abnormal lymph nodes have also been identified in patients with *Kikuchi's disease*, a benign self-limited process lasting no more than 3 months and usually occurring in people under 30 years of age.¹⁶⁷ Affected patients usually present with asymptomatic lymph node enlargement. One third of patients experience fevers. Only rarely are other signs and symptoms (e.g., weight loss, diarrhea, chills, sweating) present. On CT examination, patients generally have increased numbers of normal-sized lymph nodes. Cervical, axillary, and inguinal lymph nodes are commonly affected. Retroperitoneal lymph node involvement is not common but in rare instances may represent an isolated site of disease.

Abnormal Retroperitoneal Lymph Nodes Simulating Normal or Abnormal Vascular Structures

Occasionally, abnormal pelvic lymph nodes may demonstrate contrast enhancement similar to that of adjacent vessels. This may be confusing and may lead to misdiagno-

Figure 43-58. Collateral vessels mimicking "borderline"-sized to mildly enlarged lymph nodes in a patient with upper abdominal inferior vena cava occlusion. Unenhanced CT scan also demonstrates the presence of subcutaneous collateral vessels (arrowheads).

sis of an abnormal lymph node as a dilated vessel. As mentioned earlier, such abnormal enhancement has been seen in patients with NHL, Kaposi's sarcoma, various metastatic neoplasms, and the hyaline-vascular type of Castleman's disease.

Mimics

A variety of retroperitoneal structures can be confused with enlarged retroperitoneal lymph nodes, including collateral vessels (Fig. 43-58), dilated lymphatics, retroperitoneal hemorrhage, retroperitoneal fibrosis, and primary retroperitoneal tumors.²⁶⁹ Usually, the distinctive features of each abnormality allow the radiologist to determine that the retroperitoneal masses do not represent pathologic lymph nodes.^{110, 204}

Primary Retroperitoneal Neoplasms

Primary retroperitoneal neoplasms, rare tumors originating in the retroperitoneum, are generally derived from mesenchymal cells, neurogenic cells, or embryonic rests. Although these neoplasms usually present in middle-aged patients, they have been encountered in all age groups. These neoplasms do not produce symptoms until they are quite large, probably because they are able to grow unimpeded in the retroperitoneal space without compromising adjacent organ function.^{94, 197} The average size of malignant tumors ranges from 11 to 20 cm and of benign tumors, from 4 to 7 cm.¹³⁴

Malignant Neoplasms

Most primary retroperitoneal tumors are malignant.^{90, 91, 134, 251} The frequency of diagnosis of the various malignant retroperitoneal tumor cell types depends on the pathologist's classification system.

Liposarcomas are considered by many to be most frequent,^{44,90} although in some studies, *malignant fibrous histiocytomas* are more commonly diagnosed.¹³⁴ *Leiomyosarcomas* are encountered slightly less often, and a variety of other malignancies (*fibrosarcomas*, *teratomas*, *rhabdomyosarcoma*, and *hemangiopericytomas*) are seen only occasionally.

Although identification of a specific cell type on CT scans or MR images is not of any help in determining treatment or prognosis, several primary retroperitoneal tumors demonstrate CT and MRI characteristics that allow diagnosis of a specific cell type to be made.

The preferred treatment of all primary retroperitoneal malignancies, regardless of cell type, is surgical resection, provided that the neoplasms are not widely metastatic. Additionally, only tumor grade and resectability affect prognosis. Nonetheless, the CT and MRI characteristics of specific primary retroperitoneal malignant cell types have been described in many earlier reports and are briefly reviewed here.

Liposarcomas

CT or MRI can suggest a diagnosis of liposarcoma when fat is detected within a retroperitoneal mass (Fig. 43–59). Fat in liposarcomas can often be detected because it demonstrates characteristically low attenuation on CT scans (measuring -10 HU or less). Fat can also be identified by its high T1-weighted and high T2-weighted signal intensity on spin-echo MRI images and by signal loss on fat-saturated, T1-weighted, spin-echo MRI images.

The amount of identifiable fat in liposarcomas varies widely. It is nearly always seen in patients with well-differentiated (lipogenic) liposarcomas (which usually also contain a minimal amount of material showing soft tissue attenuation).⁴⁴ Although well-differentiated sclerosing liposarcomas, intermediate-grade myxoid liposarcomas, and high-grade pleomorphic or poorly differentiated liposarcomas may contain recognizable fat, these neoplasms sometimes show only soft tissue attenuation on CT except for

Figure 43–59. Liposarcoma. Nondynamically enhanced CT scan shows a huge liposarcoma demonstrating heterogeneous attenuation. The tumor contains components that show fat and soft tissue attenuation.

Figure 43–60. Liposarcoma. Nondynamically enhanced abdominal CT scan reveals a large area of fluid attenuation (FI) surrounded by fat.

occasional areas that show near-water attenuation, which represent necrosis.^{127, 153} More rarely, some retroperitoneal liposarcomas contain areas of homogeneously dispersed soft tissue and fatty elements, which average to water attenuation, thereby causing these regions to look cystic (Fig. 43–60).⁴⁴

Definitive differentiation of retroperitoneal liposarcomas, (particularly of the lipogenic type, from benign lipomas is not possible with CT or MRI, although some CT or MRI findings suggest that a fatty mass is more likely to be malignant than benign. These findings include identification of soft tissue septa more than 2 mm thick within a fatty retroperitoneal mass, septal irregularity or bulging, and obvious enhancement.¹⁰⁶

Differentiation of liposarcoma from lipoma may be difficult even for the pathologist. Percutaneous biopsy and evaluation of the resected tumor may not resolve the issue. For this reason, many surgeons and oncologists rely on clinical findings to determine whether a fatty tumor should be considered benign or malignant. Since malignant fatty tumors of the retroperitoneum—in contrast to those in the extremities—are much more common than benign fatty tumors, a fatty retroperitoneal tumor should generally be considered to be a liposarcoma and should be resected.

Leiomyosarcomas

Leiomyosarcomas are large, heterogeneous masses (Fig. 43–61). They often have low-attenuation or high T2-weighted-signal intensity components that represent necrosis and do not contain fat or calcification.¹³⁴ Although their appearance is never distinctive, their heterogeneity (as well as that of other retroperitoneal sarcomas of soft tissue attenuation) can be contrasted with the homogeneity usually found in the large lymphomatous masses with which they may otherwise be confused. In one series, 11 of 12 large homogeneous retroperitoneal masses were lymphomas and 20 of 26 heterogeneous soft tissue masses were retroperitoneal sarcomas (9 of these being leiomyosarcomas).⁴⁴

Figure 43-61. Leiomyosarcoma. Contrast-enhanced CT image at the midabdomen level in a 65-year-old man shows a large retroperitoneal mass (M) on the right. At surgery, this mass, which was subsequently determined to represent a leiomyosarcoma, was found to have invaded the inferior vena cava and right kidney. Any non-fat-containing primary retroperitoneal malignancy cell type may have this appearance.

Malignant Fibrous Histiocytomas

Malignant fibrous histiocytomas are often high-grade tumors. These tumors are usually visualized with CT scans and MRI as large, heterogeneous soft tissue-attenuation masses containing areas that show low attenuation or high T2-weighted signal intensity, probably representing necrosis.²²⁰ The appearance is usually not distinctive; however, up to 25% of malignant fibrous histiocytomas contain dystrophic calcification, a finding that is extremely uncommon in other retroperitoneal malignancies (Fig. 43-62).¹³⁴

Figure 43-62. Malignant fibrous histiocytoma. Contrast-enhanced CT image obtained through the abdomen in a 61-year-old man shows a large heterogeneous mass (m) anterior to the right kidney and posterior to the liver. Although many primary retroperitoneal malignancies can appear heterogeneous, the presence of calcification (arrow) suggests the specific diagnosis of malignant fibrous histiocytoma.

Hemangiopericytomas

Hemangiopericytomas are thought to originate from blood vessel walls. These tumors, not surprisingly, are very vascular and tend to demonstrate brisk enhancement on dynamic bolus CT or gadolinium-enhanced MRI studies.⁷⁶ Such enhancement is not seen with most other primary retroperitoneal malignancies. In one report, 1 of 17 hemangiopericytomas also contained amorphous calcification.⁷⁶

Primary Extragenadal Germ Cell Tumors

Only 1% to 10% of germ cell tumors originate outside the gonads, and most of these occur in the mediastinum. For this reason, the testes and ovaries should be carefully examined and imaged in any patient presenting with a retroperitoneal germ cell tumor because it is more likely that this represents metastatic disease in retroperitoneal lymph nodes than a true primary neoplasm.

Primary extragenadal germ cell tumors tend to affect young adults in their 20s and 30s.^{24, 54, 187} They are commonly heterogeneous and usually show soft tissue attenuation, making them indistinguishable from most other primary retroperitoneal neoplasm cell types (Fig. 43-63). When teratomatous elements are present, however, these tumors may contain distinctive combinations of fat, calcification, and fluid. These three elements are not typically seen together in other primary retroperitoneal neoplasms.

Other Malignancies

Fibrosarcomas and *neurofibrosarcomas* are tumors that show soft tissue density on CT scans, with attenuation values equal to or just below that of muscle. They are usually heterogeneous and thus identical in appearance to leiomyosarcomas as well as some liposarcomas and malignant fibrous histiocytomas.¹³⁴

Neuroblastomas and *ganglioneuroblastomas* often contain calcification. These two types of neoplasms are usually seen in children.¹³⁴

Rhabdomyosarcomas are quite rare and are also seen in pediatric patients. They can be quite heterogeneous.⁴⁴

Occasionally, *primary retroperitoneal adenocarcinomas* are encountered. These neoplasms are also usually heterogeneous soft tissue masses and do not have a characteristic appearance.

Benign Neoplasms

Benign primary retroperitoneal neoplasms are rare and, except for neural tumors in symptomatic patients with neurofibromatosis and paragangliomas, are usually diagnosed at surgery. Unlike surgery for many patients with primary malignant retroperitoneal neoplasms, surgery in patients with benign tumors is curative.

Most benign lesions tend to originate from neural tissue or neural crest remnants. For example, in one series, 22 of 31 benign neoplasms were paragangliomas, neurofibromas, neurilemmomas, or ganglioneuromas.¹³⁴

Paragangliomas

About 10% of all pheochromocytomas are extra-adrenal; most of these extra-adrenal pheochromocytomas, or para-

Figure 43–63. Extragonadal germ cell tumor. Contrast-enhanced CT scan from a 33-year-old man demonstrates a large, predominantly low-attenuation mass (arrow) in the paracaval region of the retroperitoneum. The differential diagnosis includes any primary retroperitoneal neoplasm.

gangliomas, lie in the retroperitoneum. The most common site is the para-aortic region, from the level of the adrenal glands to the aortic bifurcation; the latter is where the organ of Zuckerkandl is found.

Only some patients have the classic symptoms of episodic headaches, palpitations, and diaphoresis, and some patients have asymptomatic hypertension. Thus, some paragangliomas may not be clinically active. In one report of 31 tumors in 28 patients, 24 patients had hypertension, although 14 were asymptomatic; however, catecholamine levels were elevated in all 18 patients studied.⁹⁸

Although most paragangliomas are benign, a small minority (e.g., 4 of 28 patients in the preceding series) are considered malignant. A diagnosis of malignancy is usually difficult for a pathologist to make on the basis of histologic analysis of the tumor cells; it is usually necessary to demonstrate local organ invasion or distant metastases.

CT and MRI usually show paragangliomas to be well-defined soft tissue masses in the immediate para-aortic region. A retroperitoneal mass not located adjacent to the aorta probably does not represent a paraganglioma. Most small paragangliomas are homogeneous; however, the more frequently encountered larger lesions are commonly heterogeneous because they can undergo central necrosis or hemorrhage and they may even contain calcification.⁶³ On MR images, adrenal pheochromocytomas and paragangliomas often demonstrate extremely high signal intensity on T2-weighted images.⁶³ Occasionally when hemorrhage is present within a paraganglioma, a ring of lower signal intensity can be seen on T2-weighted images, probably related to hemosiderin deposition.

Paragangliomas are generally hypervascular, and most enhance briskly after injection of IV contrast material; however, because ionic iodinated IV contrast material may promote catecholamine release and subsequent hypertensive crises in patients with adrenal pheochromocytomas and extra-adrenal paragangliomas, these contrast agents are not administered routinely if these patients are not receiving α -adrenergic blocking medication. These paragangliomas are usually quite large at the time of diagnosis, however, and are easily detected even on unenhanced CT scans. The effect of gadolinium-based contrast material on catecholamine release has not been well studied.

The likelihood of precipitating catecholamine release is

greatest during percutaneous biopsy. Thus, biopsy in patients who have not received α -adrenergic blocking medication is absolutely contraindicated.

Neurofibromas

Neurofibromas are commonly retroperitoneal in location and are often seen in patients with neurofibromatosis.¹³⁴ Nerves generally course directly through these tumors and thus cannot be dissected away from them. For this reason, percutaneous biopsy of neurofibromas may be extremely painful. Surgical resection can be performed, but involved nerves will be damaged.

When imaged on CT, neurofibromas are seen as well-defined, sharply marginated, homogeneous masses that demonstrate near-water attenuation.^{16, 134} This low attenuation reflects averaging of soft tissue and the extensive intracellular fat contained in these neural sheath tumors.

These neoplasms are often located adjacent to the vertebral column or deep to the psoas muscles (Fig. 43–64). Adjacent bone, particularly the neural foramina, may be smoothly eroded. Malignant degeneration can occur and is suggested if the mass is heterogeneous, demonstrating atypical soft tissue and cystic areas, as noted by Bass and coworkers.¹⁶ Change in morphology or in size of a neurofibroma on sequential CT scans also suggests malignant degeneration.¹⁶

Neurilemmomas

Neurilemmomas or schwannomas are encapsulated tumors arising from peripheral nerve sheaths, usually seen in young to middle-aged adults.¹²⁶ Although most of these tumors are benign, malignant neurilemmomas have been reported.⁹⁷ Neurilemmomas most often occur in the soft tissues of the head and neck and in the extremities. Less commonly, the retroperitoneum is involved. Nerve fibers do not traverse neurilemmomas but instead are usually confined to the capsule of these tumors. Thus, often neurilemmomas can be surgically dissected away from adjacent nerves and removed.

On CT and MRI scans, neurilemmomas usually appear as heterogeneous soft tissue masses. Although they may contain cystic areas, they usually have large solid components. Thus, in comparison with neurofibromas, their ap-

Figure 43-64. Plexiform neurofibromas in a 28-year-old man with type I neurofibromatosis. *A*, Low-attenuation masses are identified on this contrast-enhanced CT image within and lateral to the psoas muscles. *B*, A more caudal CT scan reveals plexiform neurofibromas in the presacral space in the pelvis as well as within the spinal canal. Neurofibromas in the spinal canal are expanding the sacral foramina.

pearance is nonspecific. They are usually primarily of soft tissue attenuation on CT. Most neurilemmomas are isointense on T1-weighted, spin-echo MR images and very hyperintense on T2-weighted images.⁹⁷ No CT or MRI features permit distinction between less aggressive and more aggressive neurilemmomas.⁹⁷

Teratomas

The teratoma is one of the easiest tumors to characterize radiographically. This congenital neoplasm contains components of all three germ layers. CT may demonstrate calcification or even osseous elements. Fat-attenuation components may be visualized on both CT and MRI. A fat-fluid level, representing fat that floats on a denser layer of fluid and debris, is occasionally present (Fig. 43-65).⁶⁷ Sometimes, a dermoid plug is seen as a soft tissue mass projecting from the wall into a cystic cavity.⁶⁷

Although the incidence of malignant degeneration is

small (<1%), teratomas are usually removed because their continued growth can lead to complications (e.g., rupture, infection, torsion).⁶⁷ Even benign teratomas may adhere to adjacent structures.

Malignant degeneration is more common in postmenopausal women and usually occurs in the dermal plug. Although microscopic invasion cannot be excluded, CT or MRI visualization of an intact fat plane around the tumor usually indicates that the capsule has not been penetrated and that the tumor has not invaded and is not adherent to adjacent structures. Absence of a fat plane around the tumor does not necessarily indicate local invasion or adherence. This finding may be observed in the absence of any adjacent organ involvement, particularly in thin patients.

Lipomas

Lipomas are well-defined neoplasms composed of mature fat cells and bounded by a thin capsule. Except for

Figure 43-65. Teratoma. Contrast-enhanced abdominal CT scan reveals a large heterogeneous teratoma in the midabdomen of a 24-year-old woman. The teratoma contains elements that show the attenuation of calcification, soft tissue, fluid, and fat. A fat-fluid level can be seen in one component (arrows).

fine septa that may be seen traversing lipomas, they are relatively homogeneous and show fat density (Fig. 43–66).²⁶¹ As discussed, retroperitoneal lipomas can never be distinguished from lipogenic liposarcomas by the radiologist, by the surgeon, or often even by the pathologist.

Hemangiomas

Hemangiomas are unusual benign retroperitoneal tumors. On CT scans, they demonstrate soft tissue density. Unlike most retroperitoneal masses, they enhance briskly with IV contrast material. They may contain calcification.

Other Benign Neoplasms

Other benign retroperitoneal tumors, encountered only extremely rarely in adults, include lymphangiomas, desmoid tumors, retroperitoneal xanthogranulomas, granular cell tumors, sclerosing fibromas, xanthofibromas, and lymphangiomyomas.^{91, 100, 189, 241, 260}

Lymphangiomas are usually smooth, well-defined, near-water-attenuation masses (Fig. 43–67), most commonly discovered incidentally in young children. Desmoid tumors are masses that show soft tissue attenuation. Retroperi-

toneal xanthogranulomas, representing either a local inflammatory reaction or a true benign neoplasm,¹⁰⁰ lymphangiomyomas (seen in a patient with lymphangioleiomyomatosis),²⁴¹ and other unusual benign masses have been encountered in only a few patients.

No distinguishing characteristics of these masses have been identified. The CT and MRI appearance of all of these lesions is nonspecific, showing inhomogeneous soft tissue attenuation and soft tissue signal intensity. Thus, the diagnosis of these entities before biopsy or surgery is not possible.

Imaging at Presentation

CT and MRI are the imaging modalities of choice for evaluation of patients with known or suspected retroperitoneal masses. When large retroperitoneal masses are detected by CT or MRI, the differential diagnosis usually includes retroperitoneal neoplasm, lymphoma, and occasionally retroperitoneal lymph node metastases and retroperitoneal fibrosis. Rarely, hematoma and infection can produce retroperitoneal masses.

Figure 43–66. Retroperitoneal lipoma. *A*, Enhanced CT image reveals a fatty attenuation mass in the left retrorenal region (*arrow*) of a 47-year-old woman. The mass contains multiple soft tissue attenuation septations. *B*, T1-weighted MR image reveals the mass (*arrow*) to be of high signal intensity, similar to that of fat elsewhere in the retroperitoneum and in the subcutaneous tissues. *C*, Fat-suppressed, gadolinium-enhanced coronal image shows that the mass (*M*) has lost signal intensity, confirming that it contains a large amount of fat. At surgery, the mass was found to be a lipoma, although on the CT and MRI images, it is indistinguishable from a liposarcoma.

Figure 43-67. Retroperitoneal lymphangioma. CT scan demonstrates a large water-attenuation mass in the left para-aortic region of the retroperitoneum in an asymptomatic 71-year-old man. A thin rim of calcification along the periphery of the mass suggests that it has been present for a long time. The mass was resected. Pathologic examination confirmed the diagnosis of lymphangioma.

Percutaneous biopsy, which is often technically easy to perform because of the large size of these masses, can be extremely helpful in differentiating among these possibilities. Biopsies should be obtained with cutting or core needles because pathologic analysis often requires histologic samples, and distinction from lymphoma is more easily made.¹⁹⁷ As already noted, pathologists may have difficulty distinguishing benign from malignant retroperitoneal tumors even when surgical specimens are obtained, and clinical behavior (e.g., presence or absence of adjacent organ invasion and distant metastases) may be used to classify a tumor as benign or malignant.

Although biopsy may also permit identification of the cell type of a primary retroperitoneal tumor, treatment and prognosis are *not* affected by specific cell type. All primary retroperitoneal neoplasms must be treated surgically if possible (see later). Furthermore, only tumor resectability and grade affect patient survival.^{3, 23, 235} Patients with completely resected tumors and with low-grade tumors are most likely to live the longest.

Once the diagnosis of primary retroperitoneal neoplasm has been made, presumably by percutaneous biopsy, the CT or MRI examination should be reviewed to determine tumor location and extent. Primary retroperitoneal tumors tend to directly invade adjacent structures, and multiorgan removal may be necessary during subsequent surgery. For this reason, it is essential to determine which organs are proximal to the neoplasms and which are definitely or possibly invaded by tumor. In theory, MRI has an advantage over CT because of its ability to image in coronal and sagittal planes and thus to better define the relationship of the tumor mass to the abdominal organs and vasculature.

CT and or MRI studies should be performed through the chest, abdomen, and pelvis. This is because patients

must be assessed for possible regional or distant metastases, such as separate enlarged retroperitoneal lymph nodes, liver lesions, and lung nodules. Whereas extremity sarcomas usually metastasize to the lungs first, retroperitoneal sarcomas frequently metastasize to other abdominal organs, before or in addition to the lungs.

Treatment

Most primary retroperitoneal neoplasms in adults are treated surgically. Complete removal of the mass is preferred; however, in many patients with both benign and malignant tumors, only debulking is possible. When complete resection is performed, benign neoplasms are cured; however, recurrences are common in patients with malignant primary retroperitoneal neoplasms, even when initial surgical resection is believed to have been complete.⁸⁷

When complete resection cannot be performed, chemotherapy and/or external beam radiation of malignant tumors may be used, although each of these techniques has limited effectiveness in most patients.^{37, 73, 146, 239} Fortunately, because many malignant retroperitoneal neoplasms are relatively slow-growing, patients with unresectable tumors may still live for many years after the initial surgery.⁸⁷

Imaging after Surgery

Tumor recurrences frequently develop relatively soon after surgery, even when the initial resection was believed to have been curative. For example, in one series of 33 patients with recurrent primary retroperitoneal malignancies, 25 recurred within the first 2 years.⁸⁷ Interestingly, recurrences developed at similar time intervals in patients with high-grade tumors and in those with low-grade tumors.

Given the limited benefit of chemotherapy and radiation therapy, when recurrences are detected, the treatment of choice is usually additional surgery. Tumor re-resection may be curative; however, re-recurrences often develop, which may be treated with still more surgery. It is not unusual for second and even third debulking procedures to be performed.

Given the high rate of tumor recurrence, patients with surgically treated primary retroperitoneal malignancies are usually followed closely with regular cross-sectional imaging by either CT or MRI. Because the likelihood of completely resecting a tumor recurrence is highest if the recurrence is small when detected, it is essential to identify recurrent tumor masses as early as possible.⁸⁷

Since tumor recurrences are most often located in the operative bed, this region must be carefully evaluated on follow-up CT or MRI examinations. Next, other intra-abdominal sites (e.g., peritoneum, mesentery, liver) and the lungs should be scrutinized.

Although recurrent tumor masses usually have CT or MRI characteristics that are similar to those of the original neoplasm, tumors may recur at higher grades or with different morphology. In one study, for example, four of eight recurrent liposarcomas that initially contained identifiable fat on CT recurred as masses of entirely soft tissue attenua-

Figure 43–68. Recurrent liposarcoma. Contrast-enhanced CT scan demonstrates recurrences of a liposarcoma (m) in the right hemiabdomen of a 57-year-old woman 5 years after the initial resection. Surgical clips from the previous resection surround the tumors. The recurrent tumors have an attenuation similar to that of uninvolved adjacent retroperitoneal fat. When liposarcoma recurrences are small, they can be difficult to identify for this reason.

tion.⁸⁷ Detection of recurrent liposarcomas may also be a problem because it is occasionally difficult to distinguish normal retroperitoneal fat from fat in a recurrent tumor mass (Fig. 43–68).⁸⁷ In many instances, however, the fat in the recurrent tumor differs slightly in attenuation from normal, uninvolved fat.⁸⁷

Retroperitoneal Fibrosis

Retroperitoneal fibrosis, a rare inflammatory and fibrotic process, most frequently involves the caudal aspect of retroperitoneum. The estimated prevalence is about 1 to 2 cases per 100,000 people each year.^{4, 185} It usually affects middle-aged to elderly men but has also developed in women and children.^{85, 257}

Pathology

Early retroperitoneal fibrosis is characterized by proliferation of fibroblasts, infiltration of acute inflammatory cells, and proliferation of capillaries, all of which are surrounded by collagen fibers.²¹⁹ Immunohistochemical studies of inflammatory tissue reveal the predominant cell type to be B lymphocytes and T-helper cells.^{124, 199} Usually, a high fluid content characterizes the early stage.

Over time, the cellular activity in the retroperitoneal plaque diminishes substantially; fibrosis develops, and the collagen becomes hyalinized and much more tightly packed. Vascularity is decreased,²¹⁹ and fluid content becomes minimal.⁴ On gross inspection, long-standing retroperitoneal fibrosis appears as a characteristic gray-white plaque of woody consistency that envelops the aorta and the IVC. Although in many patients the chronic phase of the disease is characterized by this fibrotic process, in some

patients active inflammation may persist in addition to the fibrotic changes.

Etiology

In up to 70% of cases, retroperitoneal fibrosis is considered to be *idiopathic*. In most patients with the idiopathic form of disease, it is thought that the process develops as an immune response to atherosclerotic changes in the abdominal aorta.^{4, 124} One substance thought to elicit this immune response is an insoluble lipid called *ceroid*, which is commonly detected in macrophages in the aortic adventitia or in periaortic lymph nodes. Indeed, immunoglobulin G has been found in ceroid.^{124, 170, 198} Another substance that may also be able to elicit an antibody response is oxidized low-density lipoprotein.

Evidence that many cases of idiopathic retroperitoneal fibrosis might be caused by an anti-atherosclerotic immune response is supported by the fact that most of the patients are men in the fifth to seventh decades of life, individuals who tend to have atherosclerotic disease.¹²⁴ The nature of this autoimmune response, however, is unclear, because some patients are children without atherosclerotic disease. Furthermore, retroperitoneal fibrosis does not develop in all patients with atherosclerosis. Autoantibodies to ceroid have been identified in older patients with atherosclerosis and without retroperitoneal fibrosis.¹²⁴

Retroperitoneal fibrosis may also develop around AAAs. This perianeurysmal fibrosis is also thought to represent an autoimmune reaction to the atherosclerotic changes in the dilated abdominal aorta, similar to that occurring around nondilated atherosclerotic aortas.

Of the many other known benign causes of retroperitoneal fibrosis, the most common is ingestion of one of a variety of medications, including methysergide, β blockers, methyl dopa, hydralazine, antibiotics, and some analgesics. Benign diseases that may elicit retroperitoneal fibrosis include the following^{4, 41, 144}:

1. Various systemic infections (e.g., tuberculosis, syphilis, actinomycosis, brucellosis, fungal infections).
2. Focal inflammatory or infectious conditions (e.g., diverticulosis, appendicitis, extravasation from the urinary tract).
3. Previous surgery or radiation treatment.
4. Trauma.
5. Retroperitoneal hemorrhage.
6. Marfan's disease.
7. Inflammatory bowel disease.

In a small minority of patients, malignant processes (primary neoplasms or metastatic disease) can provoke an extensive desmoplastic reaction in the retroperitoneum that cannot always be distinguished from benign retroperitoneal fibrosis. Tumors found to produce such a reaction include carcinoid and malignancies from the stomach, breast, ovary, and prostate gland.^{157, 243}

Associated Processes

Associations have been reported between retroperitoneal fibrosis and a variety of inflammatory processes that can

occur elsewhere in the body, such as Riedel's thyroiditis, fibrosing mediastinitis, mesenteric fibrosis, and rheumatoid arthritis.^{4, 193, 257}

Clinical Presentation

Patients with retroperitoneal fibrosis typically present with back pain and may have a history of fatigue and weight loss.⁴ Symptoms or signs may be present that relate to compression of retroperitoneal structures, of which the ureters are the most commonly involved. Although ureteral obstruction is often clinically silent, some patients have flank pain or tenderness; others have oliguria or even anuria. Extrinsic narrowing of the IVC can cause lower extremity swelling with or without associated deep vein thrombophlebitis.

Occasionally, the distal abdominal aorta can be so severely compressed that vascular insufficiency may occur in the lower extremities, bowel, or kidneys.⁴ Retroperitoneal fibrosis may be extensive and may spread into the perirenal space or pelvis. One patient with retroperitoneal fibrosis presented with a symptomatic, constricting mass involving the proximal rectum.⁸⁹

Laboratory studies usually demonstrate significant elevation of the ESR. Blood urea nitrogen and creatinine levels may be elevated in patients with ureteral involvement.^{4, 41, 144} Leukocytosis may also be present.

CT and MRI Technique

CT and MRI represent the two modalities of choice for imaging patients with known or suspected retroperitoneal fibrosis.

Computed Tomography

CT is best performed throughout the abdomen and pelvis at contiguous 7- to 10-mm intervals after administration of oral and IV contrast material; however, when renal function is compromised (usually because of the retroperitoneal fibrosis) or another contraindication to intravascular contrast material administration, unenhanced scans should be obtained.

The CT appearance of retroperitoneal fibrosis ranges from minimal periureteral stranding to large lobulated masses obliterating the fat planes between the aorta and the IVC (Fig. 43–69).¹³⁰ The classically described medial deviation of the ureters, with respect to the lumbar vertebral pedicles, is identified only in some patients with retroperitoneal fibrosis. Additionally, this finding can also be seen in a minority of normal patients.²²⁴ Some studies have been unable to detect any difference in ureteral position in patients with retroperitoneal fibrosis when compared with normal patients.⁴

After IV contrast material administration, the fibrotic mass of retroperitoneal fibrosis typically demonstrates obvious enhancement. This enhancement can be seen with both benign and malignant causes of retroperitoneal fibrosis.⁴

In many instances, retroperitoneal fibrosis cannot be distinguished on CT scans of enlarged conglomerate lymph

Figure 43–69. Retroperitoneal fibrosis. Contrast-enhanced CT scan shows a confluent, plaque-like, soft tissue attenuation mass surrounding the proximal common iliac arteries in a 49-year-old patient. The mass was later found to represent retroperitoneal fibrosis.

nodes in patients with metastatic disease (Fig. 43–70); however, several features have been identified that, when present, suggest retroperitoneal fibrosis as the most likely diagnosis. Metastases often have a masslike configuration. Retroperitoneal fibrosis tends to be located at the level of the L4 vertebral body and to be plaque-like and infiltrating rather than nodular.^{29, 130, 219} Metastatic neoplasms often displace the aorta and IVC as well as the ureters. Conversely, retroperitoneal fibrosis usually surrounds (rather than displaces) the anterior and lateral aspects of the great

Figure 43–70. Retroperitoneal lymph node metastases mimicking retroperitoneal fibrosis. Contrast-enhanced CT scan demonstrates a conglomerate soft tissue mass of lymph nodes enlarged by tumor that surrounds the partially calcified abdominal aorta in a 75-year-old man with metastatic prostate cancer. The CT appearance is quite similar to that of retroperitoneal fibrosis.

vessels, although rarely, benign retroperitoneal fibrosis may cause anterior displacement of the aorta to a moderate extent.⁵³

Other diseases with a CT appearance similar to that of retroperitoneal fibrosis include lymphoma, infection (with resultant lymph node enlargement), primary retroperitoneal neoplasms, amyloidosis, and hemorrhage.^{4, 130} Occasionally, some of these processes demonstrate features suggesting a specific diagnosis. Enlarged lymph nodes from lymphoma are often centered more cephalad in the retroperitoneum and may be bulkiest at the level of the renal hila. Malignancies and infectious processes may invade and destroy adjacent bones or organs. Acute hemorrhage often shows high attenuation on unenhanced scans; it also infiltrates between the fascial planes in a characteristic fashion. Neoplasms may grow more quickly than retroperitoneal fibrosis, so that if a substantial increase in mass size is noted on sequential scans, malignant disease is much more likely.

Magnetic Resonance Imaging

MRI should be performed using at least three sequences. Both T1-weighted and T2-weighted spin-echo (or fast spin-echo) and gadolinium-enhanced images are recommended. MRI may be the study of choice for evaluating patients with suspected retroperitoneal fibrosis because it has two important advantages over CT.

The relationship of the mass to the great vessels is easily visualized on MRI. Whereas masses and vessels can have identical attenuation values on unenhanced CT, flow void in vessels on spin-echo MRI sequences allows for their identification even when they are surrounded by extensive tissue.

MRI can also be used in the coronal and sagittal planes, again facilitating evaluation of the relationship of retroperitoneal fibrosis to the retroperitoneal vasculature.

Additionally, MRI can sometimes suggest the specific diagnosis by detecting the low signal intensity of the mass on T2-weighted images. Since mature fibrosis contains much collagen and little cellularity and fluid, it is not surprising that long-standing retroperitoneal fibrosis commonly shows low signal intensity on T2-weighted images (Fig. 43–71).^{4, 10, 141, 182, 278} Unfortunately, because acute benign retroperitoneal fibrosis, with its greater cellularity and fluid content, has intermediate or high signal intensity on T2-weighted sequences and because chronic retroperitoneal fibrosis with continuing active inflammation has intermediate or high signal intensity on T2-weighted sequences, the MRI characteristics may not be typical.^{4, 182}

In summary, a specific diagnosis of benign retroperitoneal fibrosis can probably be offered for any patient who has a retroperitoneal mass that shows low signal intensity on both T1-weighted and T2-weighted images. High or intermediate signal intensity on either T1-weighted or T2-weighted images is not specific.

Percutaneous Biopsy

As can be seen, the definitive diagnosis of retroperitoneal fibrosis often cannot be made by any imaging study, and surgery may be required to determine with certainty whether this disease is present. Although CT-guided percutaneous biopsy is often technically feasible, a biopsy that does not result in detection of malignant cells is inconclusive. Tumor cells in patients with malignancy (with or

Figure 43–71. Retroperitoneal fibrosis. A, T1-weighted, spin-echo MR image demonstrates a low-signal-intensity, plaque-like mass (arrow) surrounding the proximal portions of both common iliac arteries (arrowheads) and the caudalmost aspect of the inferior vena cava. B, On the T2-weighted, spin-echo image, the mass (arrow) is again of very low signal intensity, a finding consistent with the presence of extensive fibrous tissue with little or no active inflammation.

without the malignant form of retroperitoneal fibrosis) may be sparse; therefore, sampling may not be successful when fine-needle aspiration or even a core biopsy is performed.

Obviously, performing surgery solely to make a diagnosis (rather than to treat) is undesirable. In some instances, patients whose clinical presentation and laboratory and imaging studies strongly suggest the diagnosis are now being treated medically, without a definitive surgical or histopathologic diagnosis, in an attempt to avoid surgery (and its attendant morbidity) solely for diagnosis.⁷¹ If response to treatment is complete, surgery is never performed.

Treatment

Benign Disease

Treatment of benign idiopathic retroperitoneal fibrosis consists of administration of high doses of corticosteroids for long periods. For example, patients may be given up to 60 mg of prednisone per day until symptoms resolve.⁷¹ The dose is tapered over several months and then maintained at a low level for 6 to 12 months. The chemotherapeutic agents azathioprine and cyclophosphamide have also been successfully employed, particularly for patients who have not responded to corticosteroids.⁷¹

In contrast, use of corticosteroids or other medications in patients with perianeurysmal fibrosis is not recommended because it is believed that resolution of the fibrotic process in these individuals places them at greater risk for aneurysm rupture. Instead, these patients should undergo elective AAA repair.

If the ureters are involved, patients may undergo open surgical or laparoscopic ureterolysis. At surgery, the ureters may be wrapped in omentum and mobilized and placed laterally over the psoas muscles or into the peritoneal cavity to remove them from the retroperitoneal inflammatory process. Alternatively, patients with ureteral involvement may respond successfully to medical treatment.⁷¹

Malignancy

Treatment of the malignant type of retroperitoneal fibrosis is palliative. Urinary diversion is recommended for patients with ureteral obstruction along with appropriate chemotherapy or radiation therapy.

Imaging after Treatment

In general, response to treatment is easily assessed by evaluating the patient for resolution of symptoms or by observing a reduced ESR or serum creatinine level (if there had been urinary tract obstruction). CT and MRI can be performed for follow-up, however, to confirm the clinical impression of response to treatment or to evaluate patients whose symptoms or laboratory results have not improved (Fig. 43-72).

In some instances, MRI may be more effective than CT in demonstrating a response to therapy, since the T2-weighted signal intensity of retroperitoneal fibrosis has been shown to decrease during treatment; this probably represents the disappearance of all active inflammation.²⁷⁸ The change in signal intensity of a retroperitoneal mass might even precede regression of mass size. Although lack of mass regression or signal intensity change may merely indicate that the retroperitoneal fibrosis has not responded to treatment, other diagnostic alternatives, including malignancy, should be considered.

Prognosis

The prognosis in patients with benign retroperitoneal fibrosis is excellent; for those with the malignant form, it is usually poor. Most patients with benign retroperitoneal fibrosis respond to initial treatment; relapse is relatively uncommon. Most patients with malignant retroperitoneal fibrosis survive for only 3 to 6 months after diagnosis.^{4, 244}

Figure 43-72. Retroperitoneal fibrosis. A, Nondynamically enhanced CT scan reveals a soft tissue mass enveloping the aorta and inferior vena cava. B, An unenhanced scan obtained after 3 months of corticosteroid therapy shows almost complete dissolution of the plaque. The increase in retroperitoneal fat is a result of corticosteroid use. (From Degesys GE, Dunnick NR, Silverman PM, et al: Retroperitoneal fibrosis: Use of CT in distinguishing among possible causes. *Am J Roentgenol* 146:57-60, copyright by American Roentgen Ray Society, 1986.)

Iliopsoas

Normal Anatomy

The psoas major muscles arise from the anterior and inferior surfaces of the transverse processes of the T12 and L1 to L5 vertebrae as well as from the adjacent vertebral bodies and intervertebral disks. They course inferiorly and fuse with the iliacus muscles before traversing under the inguinal ligament to insert onto the lesser trochanter of the femur. These bulky muscles are responsible for flexion of the thigh. When present, as is the case in 30% to 60% of individuals, the psoas minor muscles originate from the lateral aspects of T12 and L1 and travel caudad to insert onto the pectineal eminence of the ipsilateral iliac bone just anterior to the psoas major.

On routine abdominal and pelvic CT and MRI examinations, the psoas major muscles are easily visualized, lying immediately lateral to the lumbar vertebrae. Usually, the lateral aspect of the muscles is well defined by adjacent retroperitoneal fat. In children or cachectic adults, however, adjacent abdominal organs may obliterate the lateral margins of these muscles. The psoas major muscle reaches its largest cross-sectional size at the L3-L4 level. Subsequently, it thins as it fuses with the iliacus. The iliopsoas continues caudad into the thigh. It is easily visualized throughout its course.

The muscle is characterized by homogeneous attenuation, but a small linear zone of decreased density, representing fat surrounding branches of the lumbar plexus, may be identified in its lateral aspect. The psoas minor muscles may occasionally be identified as small soft tissue masses immediately anterior to the psoas major and, when observed, should not be confused with lymph nodes or retroperitoneal vessels (Fig. 43-73). The psoas minor muscles are often contiguous with the anterior aspects of the psoas major and therefore are not distinguishable as discrete structures.

Figure 43-73. Psoas minor muscles. On this contrast-enhanced CT scan, the psoas minor muscles are identified as small masses (arrows) immediately anterior to the psoas major muscles. The right psoas minor is fused with the psoas major, which is the case in many patients. The left psoas minor muscle appears more discrete.

Abnormalities of the Iliopsoas Compartment

Abnormalities of the iliopsoas muscles usually result in asymmetrical enlargement; however, some patients with neurologic or muscular disorders may demonstrate atrophy of the iliopsoas muscles on the affected side. Causes of iliopsoas compartment disease include inflammation, neoplasms, hematomas, enlargement of iliopsoas bursae, aneurysms and pseudoaneurysms, and hernias. Inflammatory processes, neoplasms, and hemorrhage may all diffusely infiltrate the iliopsoas and involve the majority of or even the entire length of the muscle.

Iliopsoas compartment disease can be evaluated with CT or MRI. Although MRI may have some theoretical advantages over CT, including its ability to easily image patients in the coronal and sagittal planes, in many instances it is no more accurate than CT in identifying the cause of an iliopsoas mass.

Some authors^{38, 275} have divided iliopsoas abnormalities into three categories based on the anatomic origin of the abnormality, as identified on cross-sectional imaging studies, in the hope that localization might help determine the cause:

1. Abnormalities intrinsic to the compartment.
2. Abnormalities extending from the spinal column, the sacroiliac joint, or hip joint.
3. Abnormalities extending from adjacent retroperitoneal structures.

Even with use of this classification, CT or MRI findings may not suggest the cause of an iliopsoas abnormality. In one study, for example, radiologists were only 48% accurate in diagnosing iliopsoas processes identified on CT when they had no knowledge of the clinical history.¹⁴³ In some instances, the diagnosis may not be possible even when imaging findings are correlated with the patient history and laboratory data.⁶⁶ Percutaneous biopsy, or occasionally even surgery, may be required for diagnosis.

Inflammatory Processes

Inflammatory processes of the iliopsoas muscles account for one third to two thirds of the psoas masses detected by CT or MRI.^{51, 66, 195, 275} Patients with inflammatory iliopsoas masses commonly have abdominal or pelvic pain and fever, although symptoms may be absent. In the overwhelming majority of cases, myositis and frank abscess develop from spread of adjacent infection of the kidneys, aortic bed, spine, pancreas, or bowel (secondary to Crohn disease, diverticulitis, or perforated colonic neoplasm). Occasionally, iliopsoas infections are complications of abdominal surgery. Only rarely does iliopsoas myositis or abscess originate in the iliopsoas muscles, probably as a result of bacterial seeding during septicemia.²⁷⁵

Commonly encountered organisms responsible for pyogenic infections include *Staphylococcus aureus* (most frequent), *Enterococcus*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Escherichia coli*, and *Mycobacterium tuberculosis*. Psoas pyomyositis has also been reported to be caused by *Salmonella enteritidis* and *Salmonella*

typhi.^{150, 271} The incidence of tuberculous spondylitis has dropped significantly over the past few decades.⁶⁶ Tuberculosis is still encountered in some patients, however, and should remain a consideration, particularly in populations at risk (i.e., people who are indigent, immunocompromised, or infected with HIV).¹⁹⁵

On CT scans, iliopsoas inflammatory masses display a variety of appearances, ranging from diffuse homogeneous enlargement of the psoas muscles to discrete masses containing areas of low attenuation (usually representing fluid) (Fig. 43–74).²⁷⁵ Punctate collections of gas are seen in only a minority of patients; when present, however, these are thought to be specific indicators of infection. In rare instances, however, air may be present in infected or even sterile necrotic tumors (either primary neoplasms or metastases).^{66, 120, 268} Calcifications are occasionally detected in inflammatory masses, particularly in patients with tuberculosis.⁶⁶ Adjacent destruction of lumbar vertebrae, which usually represents spread into the iliopsoas muscle from adjacent tuberculous or pyogenic spondylitis, may also be encountered.

MRI may be the imaging modality of choice early in the development of the myositis. The increased signal intensity on T2-weighted images, indicating muscle edema, without evidence of a focal mass, suggests the diagnosis of myositis.²⁷² A correlative finding (of decreased muscle attenuation) is only occasionally detectable on CT. Other MRI features of inflammation, which are nonspecific, include asymmetrical muscle size and areas of low signal intensity on T1-weighted images and after gadolinium enhancement.¹⁹⁵

The MRI appearance of an iliopsoas abscess is not specific. Once again, the affected muscle is enlarged. Areas of low signal intensity on T1-weighted images and of high signal intensity on T2-weighted images correspond to focal loculated fluid. Of course, any calcifications within an inflammatory mass are not directly visible on MRI studies.

CT or MRI evaluation of patients with iliopsoas infection must include scrutiny of surrounding abdominal organs for possible associated inflammatory changes. For example, associated bone destruction is easily identified.

Also, CT or MRI may be used to guide the percutaneous

aspiration and placement of percutaneous drainage catheters for definitive treatment of iliopsoas abscess, thus obviating the need for surgery.¹⁸¹ Because the CT appearances of iliopsoas phlegmon and iliopsoas abscess can be identical, it is not surprising that percutaneous aspiration of infected iliopsoas masses yields grossly purulent fluid in some instances but only solid tissue in others.²⁶⁸ Percutaneous drainage is successful only when infected fluid can be drained from the iliopsoas mass. However, the underlying cause of the infection (e.g., renal disease, pancreatitis) must be adequately treated to ensure successful management of the iliopsoas disease.

Neoplasms

Neoplasms involving the iliopsoas represent one fourth to one half of iliopsoas masses detected by CT or MRI.^{51, 66} These neoplasms most commonly result from direct invasion of adjacent primary or metastatic tumor masses. Primary retroperitoneal tumors, including liposarcomas, fibrosarcomas, and neurogenic neoplasms, can invade the iliopsoas muscle. Metastatic lymph nodes in patients with NHL, pelvic tumors, testicular tumors, renal malignancies, or malignant melanomas can invade the iliopsoas compartment. Other primary tumors that can produce metastases that invade the iliopsoas compartment are carcinomas of the cervix, ovary, colon, stomach, lung, and breast.²⁷⁴ Primary iliopsoas neoplasms (usually sarcomas) are occasionally encountered. Only rarely do isolated metastases develop in the iliopsoas compartment, probably via hematogenous spread.

Iliopsoas compartment neoplasms frequently have a CT or an MRI appearance identical to that of other iliopsoas abnormalities. The affected muscle is usually enlarged. As with abscesses, CT iliopsoas tumors may have enhancing rims and low-attenuation centers (Fig. 43–75).²⁶⁸ Calcification is unusual. Nonspecific MRI features include areas of low signal intensity on T1-weighted images, high signal intensity on T2-weighted images, and a reticulated texture.²⁷⁴

A specific diagnosis is possible only when a large

Figure 43–74. Iliopsoas abscesses. *A*, A nondynamically enhanced CT scan shows a low-attenuation mass within the right psoas muscle. At surgery, the mass contained purulent material. *B*, An unenhanced CT scan from another patient shows a large iliopsoas abscess on the left that was successfully managed by percutaneous drainage.

Figure 43-75. Malignant mass involving the iliopsoas muscles. Nondynamically enhanced CT scan shows a large, mildly heterogeneous mass (M) representing a colon cancer metastasis and infiltrating the right iliopsoas muscle. This mass would be difficult to distinguish from an abscess or a hematoma.

Figure 43-76. Spontaneous psoas hematoma in a patient receiving anticoagulant therapy. Unenhanced CT scan shows a retracting clot (C) with higher attenuation layering dependently.

amount of solid enhancing tissue is identified. Even more specific is the identification of fat within an iliopsoas mass, in which case a fatty tumor (usually a liposarcoma but occasionally a lipoma or teratoma) can be diagnosed.

Malignant iliopsoas masses are more likely to invade rather than respect fascial planes, which results in large, localized masses distorting only portions of the iliopsoas while spreading out to destroy adjacent bones and soft tissues.¹⁴³ Thus, in one study the most common CT findings were enlarged psoas muscle with irregular lesion margins and bone destruction.²⁷⁵ Unfortunately, this finding was neither highly sensitive nor specific. Iliopsoas abscesses and hematomas may also produce localized masses, and bone destruction can result from infection. Conversely, occasionally iliopsoas neoplasms may diffusely infiltrate large portions of the iliopsoas.

Hemorrhage

Hemorrhage in and around the iliopsoas muscles is another cause of iliopsoas compartment disease.⁵¹ Iliopsoas hematomas have been described in patients with hemophilia, von Willebrand's disease, thrombocytopenia, leaking AAAs or grafts, and traumatic injuries, and after femoral arteriography as well as in patients receiving anticoagulants.^{66, 111}

If bleeding is acute, an unenhanced CT scan can demonstrate high-attenuation collections within enlarged iliopsoas muscles²¹⁴ (Fig. 43-76). Fluid-fluid levels, corresponding to layering of unclotted blood components, are typically seen in patients who have received anticoagulants and in those with bleeding diatheses. Over time, the hematoma often shows progressively lower attenuation, so that after several days it can have an appearance (on a noncontrast CT scan) identical to that of an inflammatory or a neoplastic mass. Old hematomas may undergo liquefaction and develop central components that show attenuation values near that of water.

The MRI features of hematomas tend to vary more dramatically over time than the CT features. Within the

first few hours, hematomas have a nonspecific appearance on MRI examinations, demonstrating intermediate signal intensity on T1-weighted images and variable signal intensity on T2-weighted images.⁶³ Of all the iliopsoas masses, however, only hematomas can have high signal on both T1-weighted and T2-weighted sequences (within 24 to 48 hours of formation). Gradually, the T2-signal intensity begins to diminish first, so that subacute iliopsoas hematomas may have high-signal-intensity components on T1-weighted images and low signal intensity on T2-weighted images.²⁷⁴

Engelken and Ros noted that subacute hematomas may have three distinct components on T1-weighted MR images⁶³:

1. A rim of low signal intensity.
2. More central but still peripheral areas of hyperintensity.
3. A medium-signal-intensity central region.

Finally, as the hematoma ages further, it tends to become smaller. A chronic hematoma, more than 2 weeks old, generally has areas that demonstrate low signal intensity on both T1-weighted and T2-weighted sequences because of its hemosiderin content.^{63, 274}

Hematomas tend to spread between and not through fascial planes and may spread along the entire length of the iliopsoas compartment. Bone destruction is not present; thus, if bone abnormalities are identified, a diagnosis of hematoma without concomitant infection or neoplasm is unlikely. Although percutaneous biopsy is sometimes helpful in excluding other diagnoses, the clinical history and CT findings allow appropriate identification of iliopsoas hematomas in most patients.

Iliopsoas Bursitis

The iliopsoas synovial bursa lies between the musculo-tendinous junction of the iliopsoas muscle and the pelvic brim. When the bursa becomes inflamed, it may enlarge. Indeed, it has been suggested that enlargement of the ilio-

Figure 43-77. Enlarged iliopsoas bursa. Nondynamically enhanced CT scan shows an asymptomatic, low-attenuation groin mass (M) in a patient with rheumatoid arthritis. The mass represents an unusually prominent iliopsoas bursa.

psoas bursa should be included in the differential diagnosis of any groin mass.⁴⁹

The three main causes of iliopsoas bursitis are rheumatoid arthritis, acute trauma, and overuse injury; trauma and overuse are the most common. In most instances, rheumatoid arthritis appears to involve the iliopsoas bursa as an extension from the hip, although communication with the hip joint space is seen in only 15% of cases when arthrography is performed.¹¹⁹

The most common presentation is anterior hip pain and a palpable or an audible snap on motion of the muscle, the latter occurring as a result of sudden movement of the iliopsoas tendon over an adjacent bony prominence, namely, the anterior inferior iliac spine, the iliopectineal eminence, or the bony ridge of the lesser trochanter.¹¹⁹

Iliopsoas bursitis/tendinitis, or the *iliopsoas syndrome*, can produce iliopsoas compartment abnormalities. On CT

scans or MR images, the enlarged or inflamed iliopsoas bursa is usually identified as a fluid-containing structure within the iliopsoas muscle in the pelvis. Although generally rounded or ovoid in shape, it often has a slight invagination toward the hip joint (Fig. 43-77).

CT and MRI can also be used to identify a posteriorly malpositioned lesser trochanter, which can alter the course of the adjacent iliopsoas tendon and predispose patients to this condition.¹¹⁹ MRI can be uniquely useful because it occasionally reveals signal intensity changes in the iliopsoas tendon, indicating that the inflammatory process involves this structure.

Aneurysms and Pseudoaneurysms

In rare instances, atherosclerotic aortic aneurysms and lumbar artery aneurysms or pseudoaneurysms may produce iliopsoas compartment masses.¹⁰⁷ On physical examination, many patients have a pulsatile mass and a bruit. The vascular nature of these abnormalities can be identified on CT scans only if IV contrast material has been administered (Fig. 43-78). A bolus injection of contrast material, followed by dynamic sequential imaging, is required and may demonstrate the abnormal vessel in the region of the psoas muscle.

On MR images, the vascular origin of these abnormalities is easily determined, even when contrast-enhanced studies are not performed. This is because flow void can be identified on spin-echo or fast spin-echo sequences; however, a flow-sensitive set of (limited flip-angle or gadolinium-enhanced) images should be obtained. It is clearly important to image the entire course of the aorta and the iliac vessels in such patients so that the extent of the aneurysm and the presence or absence of any additional aneurysms can be determined.

It is not possible to differentiate a true aneurysm from a pseudoaneurysm in any given case; however, true iliopsoas

Figure 43-78. Lumbar artery pseudoaneurysm. A, Unenhanced scan shows a large left iliopsoas mass in a patient who had received a gunshot wound years previously. B, Arteriogram demonstrates contrast material in the center of the pseudoaneurysm (arrow).

aneurysms are extremely rare. Clinically, an atherosclerotic cause for an iliopsoas compartment aneurysm is suggested if a extensive atherosclerotic changes have occurred elsewhere in the abdomen. A pseudoaneurysm is suggested if a patient has a history of trauma or surgery, particularly if no atherosclerotic disease is seen elsewhere. Pseudoaneurysms tend to have an unusual shape.

Obviously, the possibility that an iliopsoas mass (or any visualized mass) represents an aneurysm or a pseudoaneurysm must be excluded before percutaneous biopsy is performed.

Hernias

Another rare cause of an iliopsoas compartment mass is a *retropsoas* hernia. This rare hernia occurs through a defect along the lateral border of the psoas muscle. When such a hernia is present and when bowel is involved, the bowel is noted to extend posteriorly and medially relative to the psoas muscle.

Although the diagnosis can be suspected on a small-bowel examination, CT and MRI can facilitate the diagnosis because they clearly demonstrate the abnormal posterior location of bowel.²² Usually, the loop of bowel is appropriately identified. There is a risk of misdiagnosis, however: If, on cursory review of a CT scan, the herniated loop of bowel is not opacified with oral contrast material, the abnormally located air and fluid can be mistaken for an iliopsoas compartment abscess or other iliopsoas compartment abnormality.²²
